A Technician's Tallying Machine

Keypad operation—count always visible

THE Vaness Tally is a simplified blood classifying and adding machine, designed especially for differential cell counts by the "Classical" or "Schilling" methods.

A series of ten keys are conveniently located in front of a visible tally. Each tally is an inverted U-column—when a key is pressed, two counters are recorded, one in its corresponding column and the other in the "total column." When the "total column" reaches 100, all keys are automatically locked and the reading of each separate column is its percentage. A reset key on the right side of the instrument releases the counter for further tallying.

The instrument is simple, accurate, and rapid.

Vaness Tally, \$15.00

Quick Drying

The Fisher Quick-Drying Cabinet rapidly desiccates samples and specimens in $\frac{1}{2}$ to $\frac{1}{4}$ the time required in an ordinary gravity convection oven

Rapid Dryer with many uses

FOR DRYING—

Food and Feces.

Chemical Salts.

Wet Samples.

And numerous other materials.

Utilizes Mechanical Convection

This rapid dryer utilizes mechanical convection of heat and moisture.

The air is drawn into the right side of the cabinet through an adjustable louver. It passes through the fan over two 500-watt nickel-chromium wire heaters and then over the two removable shelves and out the left side of the cabinet.

The temperature range of the cabinet is from 75° C. to 125° C. and can be manually controlled by the louver at any point within the range with a constancy of 2° C.

Made of stainless steel—heating chamber 12 by 9 by 9 inches—an “off-on” switch controls both fan and heating elements, a ruby pilot light indicates when in operation.

For 110 volts, 50-60 cycle A.C. Wattage 1100 ----- \$50.00

The amount of hot air passed through the cabinet is controlled by the louver.

Fisher Shaking Machine for the Kahn Test

Less noise greater efficiency mark these Fisher Shaking Machines as outstanding contributions to the accuracy of the Kahn Test.

They oscillate at 275 to 285 times per minute which conforms to the standardized Kahn technique.

The large machine works equally well with one to six racks.

The smaller model performs with equal efficiency with one to three racks.

Fisher Shaking Machine, 6-rack model (without racks) 110 volts A. C.\$80.00

Fisher Shaking Machine, 3-rack model (without racks) 110 volts A. C.\$70.00

(Also available for other currents.)

Six Rack Model

Silent Racks

To eliminate noise, a new rubber-coated Kahn test tube rack has been devised.

It completely eliminates the annoying clicking sound of the tubes. The racks, being rubberized, are corrosion resistant and offer a black background for precipitate observation.

Rack for holding 30 tubes, each\$2.75

Fisher-Van Slyke Manometric Apparatus

for the
Rapid and Accurate Measurement of Blood Gases

FEATURES

1. The extraction chamber is shaken by a motor mounted on the side of the illuminating box; this operates through a silent worm drive built into the motor. A flywheel gives a smooth, quiet action to the shaking—a rheostat regulates the shaking speed.
2. The rear half of the water jacket surrounding the extraction chamber is frosted, and is electrically illuminated from the rear. This light gives a diffused, even illumination to the reaction chamber and greatly facilitates reading its graduations.
3. The graduated manometer is mounted before a narrow slit in the panel. This slit contains an opal glass plate illuminated from the rear by two 40-watt tubular lamps. The graduations extend from 0 to 650 mm.
4. The extraction chamber is made of resistance glass, well annealed. The accuracy of the 0.5 ml. and 2 ml. graduation marks is within the limits specified by Dr. Van Slyke. A Certificate of Accuracy is supplied with each chamber.
5. All the wood parts are solid oak, stained and finished with acid-proof varnish, built to withstand long, hard usage.

The apparatus supplied includes the wooden parts and glass parts illustrated, motor, three illuminating bulbs, rubber tubing, one (1) each Pipettes, 0.1 ml., 0.2 ml., 1 ml., 2 ml., 3 ml., 5 ml., special thermometer, and instructions. Operates on 110 volts, A.C. or D.C.

Each \$126.00

Pittsburgh Non-Corrosive Slides

Microscope slides made from sheet glass produced by the Pittsburgh process resist corrosion, are uniform in thickness and practically free from striae.

A continuous flat sheet of practically iron-free glass is drawn directly from the tank. Slides cut from this sheet have true surfaces and a practical absence of a green tint.

An accelerated corrosion test showed that the Pittsburgh Non-Corrosive Slide was superior to the ordinary microscope slide.

Pittsburgh N-C Slides 3 x 1 inches in $\frac{1}{2}$ gross boxes—\$1.20 per gross. In original case of 25 gross—\$1.00 per gross.

A Universal Constant Temperature Water Bath

THIS water bath is thermostatically controlled, holding temperatures from that of room to 110°C . with an accuracy of plus or minus 0.2°C .

The bath is supplied with a brass rack or shelf suspended several inches above the electrical immersion heaters near the bottom of the bath. This rack is used to hold submerged specimens, containers, test-tube racks, etc., and can be lifted out at any time.

These baths can be used for the Kahn tests, Wassermann reactions, inactivation, inspissations, paraffin embedding, and other biological, bacteriological and pathological work. If desired, racks are available for any size tubes.

Three Sizes
Water Chamber
12" long 12" wide $8\frac{1}{2}$ " deep
600 watts \$125.00

Water Chamber
18" long 12" wide $8\frac{1}{2}$ " deep
1200 watts \$150.00

Water Chamber
36" long 18" wide 12" deep

American Museum Jars

(Made in U. S. A.)

in many sizes

THESE American-made jars have qualities which place them ahead of the imported jars offered in previous years. They are made of colorless glass pressed in iron molds, assuring uniform thickness of walls. This prevents distortion of the specimen. Suspension rods or frames can be laid across the recesses at the top of the jars and specimens thus hung in the fluid. This avoids the necessity of clumsy pedestal supports.

The covers are pressed from the same clear glass; each contains a small opening which acts as a vent and permits addition of preserving fluid after sealing.

The International Association of Medical Museums has recommended the various sizes which are furnished.

Size No.	1	2	3	4	5	6	7	8	10	11
Height, inside, cm.	5	10	15	15	16	20	20	20	25	25

A New Bacteria Counter

The New Bacteria Counter

A NEW and better way of illuminating the bacteria colonies together with the new 4-inch magnifier, make the Lumi-Lens the outstanding Counter of the day.*

Two 110-volt incandescent lamps one on each side of the base-housing produce oblique illumination across the Wolfhugel counter. No light blinds the eyes of the operator.

The entire area of the Petri-dish is viewed clearly with *both* eyes using the new two-lens magnifier.

Lumi-Lens with Wolfhugel Counter—\$25.00

**Duplicate counting tests of 35 individuals using 17 different combinations of counting equipment showed the best results with this method of illumination and observation. (Am. Jr. Public Health, January 2nd, 1932.)*

A Universal Constant-Temperature Water Bath

THIS water bath is thermostatically controlled, holding temperatures from that of room to 110°C . with an accuracy of plus or minus 0.2°C .

The bath is supplied with a brass rack or shelf suspended several inches above the electrical immersion heaters near the bottom of the bath. This rack is used to hold submerged specimens, containers, test tube racks, etc., and can be lifted out at any time.

These baths can be supplied with racks for any size tubes desired and are used with this addition for Kahn tests, Wassermann reactions, inactivation, inspissations, paraffin embedding, and other biological, bacteriological, pathological work.

Three Sizes

Water Chamber
12" long 12" wide $8\frac{1}{2}$ " deep
600 watts \$125.00

Water Chamber
18" long 12" wide $8\frac{1}{2}$ " deep
1200 watts \$150.00

Water Chamber
36" long 18" wide 12" deep
1800 watts \$200.00

Specimen Bottles and Carrying Racks

These Urine Specimen Bottles are specially designed for clinical laboratory and hospital routine.

Molded glass letters identify the bottle. The bottles are graduated to 7 ounces in $\frac{1}{2}$ ounce divisions.

Six blank label-caps are supplied with each bottle ("Name-Room-Date").

6-512

Easy to clean and sterilize, these bottles are today standardized equipment of many large hospital laboratories.

6-514

Carrying Rack, No. 6-514, made of galvanized metal, holds 1 to 12 of the No. 6-512 bottles.

A small container on the end of the rack holds the caps for the specimen bottles.

6-512 Urine Specimen Bottles	Per dozen	\$ 1.10
	Per gross	\$10.50
6-514 Urine Specimen Bottle Racks	Each	\$ 4.25

Modern Sterilizers

Fisher offers rugged sterilizers for the modern clinical laboratory, where closely controlled sterilization is desired.

A radial pressure-locking device prevents opening the sterilizer while under pressure.

Automatic discharge of air and condensation insures uniform temperature throughout the entire chamber.

An adjustable exhaust valve discharges into the waste pipe, not the room, and therefore does not saturate the atmosphere.

The exteriors are highly polished nickel; the interiors are heavily tinned; the stands, white enamel. The heavy copper inner chambers are provided with removable shelves.

Complete with safety valve, pressure gauge and thermometer.

Size No. -----	1	2	3
Diameter of chamber, inches ---	16	18	22
Length of chamber, inches -----	24	26	30
Diameter of door, inches -----	14	16	20
14-488 A, for 110 volts, A.C. or D.C. ...	\$488.75	\$531.25	\$701.25
14-488 B, for 220 volts, A.C. or D.C. ...	488.75	531.25	701.25

These Fisher Steam Sterilizers are obtainable with gas heating units and also for direct connections with 20 pound steam lines.

Reduced Prices -- Pyrex Petri Dishes

Lower prices and the new feature of reinforced rims, strengthened by special fire-polishing make Pyrex Petri Dishes the economical purchase for the Clinical Laboratory.

PYREX FEATURES

- 1—Observation Improved—Clear: Exceptionally true, highly polished flat surfaces.
- 2—Better resists Sterilization: Pyrex glass is heat and corrosion resistant.
- 3—Better withstands Handling: The particular properties of the glass plus the unique reinforced rims, reduce chipping and breakage.
- 4—Resists Chemical Cleaning: Neither Chromic Acid nor NaOH affects the high polish of this glass.

CLINICAL AND EXPERIMENTAL

THE MEDICINE OF THE AMERICAN INDIAN*

HARLOW BROOKS, M.D., NEW YORK CITY, N. Y.

AS PRACTITIONERS of medicine we are in this day perhaps too prone to forget the value to medicine of the work of those who have preceded us, perhaps too much persuaded that modern medicine and modern science are only of value. We forget too easily that medicine like most other things is a matter of evolution and that most of our knowledge has in fact been based on a foundation of the experience and study of ages. I wonder sometimes whether we appreciate fully how absolutely dependent we are in medicine on what has gone before. How many of us are competent to practice medicine even today on the frontier away from the manufacturing pharmacist, away from our colleagues, from our journals, and from the basic facts in particular which have evolved from the studies of centuries past.

My observation has been that the modern scientifically trained student is in large degree more and more dependent on the facts and experiences which others have gleaned. Many, if not most of our research workers must base their investigations on a foundation of evolved knowledge which we take altogether too casually and with too little respect for its origin.

How many of us are competent to even set a fracture or to treat a serious wound away from the detailed assistance of the hospital and the carefully worked out preparations which we owe to others. Briefly how many of us with all our present knowledge might successfully practice the art of physic

*An address before the Richmond Academy of Medicine, Richmond, Virginia November 22, 1932.

Received for publication, December 5, 1932.

in the stone age, entirely without the assistance which others render to us? If one but thinks of this, better if one tries to meet the emergencies of practice away from drug stores, away from hospitals, without the microscope, and without the x-ray, how would we get on?

Hence it seems to me that it is well for us to study medical evolution, to interest ourselves in the pregnant subject of medical history, to learn of, as we shall certainly come to respect our predecessors in the practice of medicine and surgery. To do this one must acquire more than a passing knowledge of archeology and ethnology; one must delve sincerely into the customs and requirements of ancient peoples. Such a study is certain to broaden our knowledge and certain also to create in us a great respect for those men and peoples who with little inherited knowledge and no literature have none the less laid the foundations of medical art and science.

How many of us appreciate what we owe to those who gave us mercury, iodides, the salicylates, digitalis, the saline laxatives, cascara and aloes, quinine, cocain, alcohol, and the sedatives of the opium group? These and many other drugs on which we daily depend were discovered and properly used by the red man. Thousands of years before Witherington was born, the Indian of the southwest used infusions of Foxglove in heart disease, and if history is to be relied upon, he used it properly.

Another point which we must always bear in mind in these studies is that modern medicine as we term it could not as it now stands have been adapted to the needs of ancient man, chiefly because modern medicine is now dependent absolutely on the assistance of the chemist, the physicist, the bacteriologist, the pharmacist, and the manufacturer. The medicine of the stone age was necessarily also of the stone age; the electric knife was not available but the keen edged flake of obsidian was, and for that surgeon who is high-minded of his present-day skill, permit me to recommend that he try in his work only such tools as the stone age supplied, and then compare his results and skill with those of the surgeon of that day. If we will properly appreciate the medicine of primitive man, we must know his needs and the facilities furnished him; they were indeed very different from those of this day.

Perhaps as a class we less appreciate the history and the archeology of our native Americans than those of any other people. All of us know of ancient Egypt, of Rome, of Greece; we are, as properly educated men, tolerably familiar with those ancient peoples, and we know a good deal of their medicine and of the basic knowledge which they evolved on which modern medicine depends absolutely and hourly. How many of us realize the fact that here in America we had a civilization which exceeded and preceded in art, mathematics, astronomy, architecture, agriculture, politics, and which certainly equalled even in theology that of any of the ancient peoples of Europe.

In Bolivia still stands, in spite of Spanish cupidity and religious intolerance, the devastated fragments of a city, greater in its architecture and in its sculpture than anything that Greece or Italy ever produced, and it preceded

the culture of these countries by at least several thousand years. How many of us realize that when the Spaniard came to America he found a civilization in certain areas which exceeded his own of that very time except in the two particulars of military organization and in navigation. For those of you who are skeptics, may I recommend that you read Mason's "Columbus Came Late," or still better for the more serious minded and studious of you, read Verrill's "Old Civilizations of the New World." For those of you who still doubt, instead of going on your next vacation to Greece or Egypt, go to Tia-huanaco in Bolivia, to Cusco, to Yucatan, Guatamala, or Honduras. Study in the museums of Lima or in the easily accessible and marvelous collections of the City of Mexico, or if still in doubt precede your own explorations by a visit to the Museum of the American Indian, Heye Foundation here in your own city. Many beautiful and marvelous things of ancient American origin are also to be seen any day in the American Museum of Natural History, any one of which must convince you that here in our own America we possessed a civilization and an art more marvelous than anything of its kind in Africa or Europe.

With this introduction permit me then to talk with you for a few moments concerning the medicine of the American Indian. At the outset it is important for you to understand that under the heading of the American Indian, a tremendous field is included. To conceive of the American Indian as a single race or people is as absurd as to speak of the Europeans as a single class group. The American Indian varies as widely in his tribal civilization standards and types as does the Italian from the Iclander. What I have to say to you this evening is chiefly of certain of the tribes with which I have been most familiar, of the Ojibways, the Sioux, the Blackfeet, the Apache, the Navaho, and something of the Pueblo people. I thus limit myself because I know so very much less of the medicine of the South American Indian including the tribes of Mexico, Honduras, Guatamala, Chili, Peru, Bolivia, of the Myas, the Guiamacs, even of the Aztecs and Preaztecs; and yet we know that these tribes exceeded in civilization, art, agriculture, architecture, sculpture, and astronomy the tribes of which I am to speak mostly tonight as much as the modern Englishman or German exceeds the Laplander or Esquimo of today. Of these tribes have sprung such heroes, statesmen as Tecumseh, as Bolivar, Pofiero Diaz, Cailles, Rubio, and others who are truly world figures and not merely citizens of one land or one people. Occasionally, as in comparison, I shall refer to the medicine of the southern Indian, drawing for my knowledge on the little that I have seen and from what I have read.

Also in passing I should like to say that inevitably the white man has lowered and befouled the Indian of whatever tribe by his religion and by his military methods. In these characteristics only, it seems to me, have we outdone the Indian; these have been the two channels through which we have "civilized" the red man.

Before it is possible to go on, may I tell you something of what the red man, whose medicine I am to speak to you of this evening, was. Perhaps I

can do no better than to quote at the outset what Colden says of the Iroquois, our predecessors in New York.*

On the death of Lieut. Governor de Laney in 1760, Colden came to New York as Governor; he was appointed Lieut. Governor in 1761. He produced a great mass of geographical, metaphysical, medical, and theological learning and literature. He was the son of a Scotch clergyman and was designed for the clergy, but he took up finally the study of medicine. He practiced after his graduation in England, for some time in Pennsylvania, and later, because of his distinction, he became surveyor general of the colony in New York. He was made a master in Chancery and received a large grant of land near the town of Montgomery in Orange County. He was regarded in England as the best informed man in the New World on the affairs of the British colonies in America. He was an early observer of the influence of climate on health. He was just and fair to the Indians, was much honored by them and was adopted by the Mohawks of Canajoharie. The books cited were apparently written to inform Great Britain on the Indian question and to stress the strength and importance of the Iroquois Federation with which he was keenly informed and sympathetic. He died at Spring Hill, near Flushing, on the twenty-first of September, 1776. His many manuscripts are safe in the archives of the New York Historical Society but little is commonly known of him now though he was for his times one of the most learned in electricity, in natural philosophy, and in history. He was the valued associate of Franklin, a correspondent of Linnaeus, Grovius and with other eminent authorities in the natural sciences. He was always keenly alive to the scientific medicine of the day though his important executive obligations required his giving up medical practice.

He says: "The Five Nations are a poor and generally called barbarous people, bred under the darkest ignorance; and yet a bright and noble genius shines through these black clouds." "None of the greatest Roman Heroes have discovered a greater love to their country or a greater Contempt of Death than these People called Barbarians have done, when Liberty came in Competition. Indeed I think that our Indians have outdone the Romans in this Particular; some of the greatest of those have we know murdered themselves to avoid Shame or Torments; but our Indians have refused to die meanly, or with but little pain when they thought their country's Honor would be at stake by it; but have given their bodies willingly to the most cruel of torments of their Enemies, to shew as they said, that the Five Nations consisted of Men, whose Courage and Resolution could not be shaken."

"Instead of virtues we have only taught them Vices, that they were entirely free from before that time." "If care were taken to implant and cultivate in them that general benevolence to Mankind, which is the first true principle of Virtue—They would no longer deserve the Name of Barbarians, but would become a people, whose Friendship might add Honor to the British Nation." "Their great Men, both Sachems and Captains, are gener-

*The History of the Five Indian Nations of Canada which are dependent on the Province of New York, and are barrier between the English and the French in that part of the World. By Hon. Cadwallader Colden. New Amsterdam Book Company, New York, 1902.

ally poorer than the common People; for they effect to give away and distribute all Presents or Plunder they get in their Treties or in War, so as to leave nothing to themselves."

The only writings which I have been able to secure of Governor Colden are concerning the history of the Indian wars and of their treaties. I have obtained nothing dealing with Indian Medicine. It is to be much regretted that a person of his medical training and scientific thought should not have written of the medical customs of these our predecessors in the medical practice of New York. It is very evident that he thoroughly respected and even admired these men. As to their political sagacity, trustworthiness and valor, he leaves little unsaid and where he recounts their cruelty and brutality, he is wont to compare it without honor to the white man with his religious persecutions and his retaliatory wars.

Clark Wissler of the American Museum of Natural History, one of our greatest living authorities on archeology and ethnology says (The American Indian): that the Indian stands out in his culture in sharp contrast to that of the old world, and that while we have replaced him in this land, we have absorbed a great deal of his culture, and that we have wrought great havoc by his withdrawal from painting, sculpture, and the decorative arts. This loss, though considerable would be small comparable to that if we were to lose from our economic life maize, cocoa, quinine, tobacco, potatoes, beans, squash, melons, and tomatoes, and what has evolved from our adaptation of their agricultural methods in the world. Irrigation, at least in this country is founded on Indian methods and procedures and their agricultural methods from the use of irrigation are still of immeasurable value to us today. I have seen beautiful irrigation systems installed by the prehistoric Indian, still in use today in Arizona, monumental systems which existed long before the advent of the white man. Wissler further says: "Imagine what would be lost to us if we could strike from our history, geography and literature all that pertains to the Indian!" The white man in many localities added but little beside iron and a more schooled and ruthless method of warfare.

Even our language, here in the new world has been in very large part taken from that of our red predecessors: we "hit the trail," we "pass over the divide," the camp fire, and the lodge circle have become endeared terms of our idiom, and a large number of us, in spite of our religious teachings still yearn to reach the "Happy hunting grounds." Our geographic names are in greater part adapted from those of the red man, our great railway systems, even our modern automobile highways for the greater part still follow the moccasin beaten pathways of the Indian, and most of our mannerisms and idioms which are typically American, evidence the survival in our culture, that of the red man. Colloquialisms and dramatic figures of American slang, poetry, and literature still portray the persistence and dramatic quality of the Indian orators, heroes, and statesmen.

In government, and particularly in the more idealistic forms expressed in altruistic communism, the world has never equalled the systems of the Pueblo peoples or that probably in vogue among the Mayas, Astecs, and

Toltecs. The League of the Five Nations in our own state of New York still represents a high water mark of organization and mutual consideration in governmental affairs. It was truly a league of nations, with ability, altruism, truth, and honesty in act as in theory.

I have already mentioned the deep impress which the Indian has made on our language. Notwithstanding the fact that the Indian peoples in the Americas have differed tremendously in traits, characteristics, in culture and in customs, as widely certainly as now exists between any of the civilized peoples of the whole world, still they possessed and still do, a mutual method of communication in the sign language which was almost universally understood and employed. It has interested me tremendously to note the strong similarity between this sign language of the Indians and that which our deaf and dumb now use. An Indian skilled in sign language, I am convinced would have little difficulty in understanding much or most of the sign language employed by the deaf and dumb, and the art of pantomime has never been more fully and beautifully demonstrated than by the orators of our primitive people.

In art, we have rarely as yet equalled that of the Indian, particularly in textiles exemplified by the beautiful and useful weaving of the South American tribes and the exquisite, when uncontaminated by white design, work of our Navahoes and Pueblos. We can never hope to equal the Indian in basketry, especially the work of the Pimas, Apache, and Supai, and the work of the ancient basket maker was never equalled, by even these artisans. In ceramics we can justly compare Indian antique work with that of the Chinese, for they have far excelled the Greeks in this work as well as in sculpture.

It is entirely inconceivable that such a people should not have had and practiced a system of medicine and surgery, comparable with their culture in other fields. The more we come to study their methods, the more do we become impressed with their skill and learning in these directions, especially in the field of traumatic surgery with which, naturally from the requirements of their habits of life, warfare and culture, they came most frequently in need.

Though I have been a student of Indian medicine since my early boyhood I know but little of the subject, but that little has created in me a feeling of great respect and admiration. Pioneer medicine in this country has been almost entirely derived from Indian methods, and I think that before I am done this evening I shall cause most of you to feel but honor and respect for the medicine of the American Indian. There are few methods of modern medicine which were not represented in kind, if not in precise technic by Indian methods, and we owe entirely to our Indian predecessors in the profession many of our most potent methods and drugs. Cesarean section, symphysiotomy, and the Credé method of placental expulsion, Verrill states (private communication) were practiced among certain of the more highly cultured tribes as those of certain districts in South and Southern America, long before Caesar was born. The same authority, corroborated by Hrdlicka and many other students of the subject, calls attention to the frequency and success of trephining of the skull and the use of artificial limbs ages before

the white man or even the Egyptians had advanced beyond the most primitive methods of medical or surgical procedure.

It is a curious and very unfortunate fact that the voluminous literature concerning Indian medicine and surgery has so very little to say concerning the practices of our most advanced and intelligent tribes, notably those of South America, of Central America and Mexico, where we know the highest types of civilization flourished, then present in the entire world. There are several reasons for this unfortunate state. Among these are the fact that most of the studies of these most advanced tribes have been made by ethnologists and archeologists who have had but little medical interest or schooling. Until we have discovered a Rosetta Stone which will unlock the secrets of the abundant records and codices of these peoples which we possess, we can expect to know only that of the medical and surgical practices of these people which has been handed down to the present descendants of these people. Yet we know that these tribes employed anesthetics for surgical procedures, notably cocaine, peyote and other drugs while the white man was a barbarian who put his wounded in war to death by "mercifully slitting the wezand."

Concerning the medical methods of our northern tribes we have much more exact knowledge from the methods of pioneer medicine which have been handed down to us and very largely also because many of the early missionaries, who were themselves more or less medically trained have recorded their observations as in the records of the Jesuit fathers. Also in very large part because the medical officers of our little army have from the very first been interested in the subject and have recorded their studies and observations in official reports. Furthermore we must accord great credit to our ethnologists and archeologists in North America who have seriously interested themselves constantly in these important matters. Men such as Hrdlicka, Wissler, Verrill, Lieutenant Bourke, Colonel Dodge and even Lewis and Clark in their journals have given a hearing to this important field of archeology which has made it possible for us of the profession to derive, concerning our more northern tribes an understanding of the matter which has been and still is of great value and considerable accuracy. May I also give some credit to the numerous amateur archeologists of our profession who have given time and study to the subject.

Considerable information must be also attributed to the most bitter enemies of Indian Medicine from the days of Cortez to the present time, the theologians who have with few exceptions mentioned but to condemn, such writers as the malodorous Cotton Mather for example. The father of this person, the Reverend Mr. Increase Mather also wrote extensively in like vein. Mathers *Magnalia*, Book III, as Halkett quaintly says, solves the Gordian knot of the matter of the origin of the American Indian most satisfactorily perhaps from the standpoint of a theologian. This reverend authority says: "The natives of the country had been forlorn and wretched heathen ever since their first herding here; and though we know not when or how the Indians first became inhabitants of this mighty continent, yet we may guess that probably the devil decoyed those miserable salvages hither, in hopes that the

gospel would never come here to destroy or disturb his absolute empire over them." The amiable Increase cites as illustrative of this archeologic gem, the statement of an Indian about to be executed for a murder committed while he was drunk, who stated that the "missionaries minded their bottle more than their Bible."

John Halkett, Esq., author of "*Historical Notes, Respecting the Indians of North America, with remarks on the attempts made to convert and civilize them*" (London, 1825), stresses the point that a natural approach to the affections of the Indians would be through the introduction of medical men instead of clergymen. This author points out the greater success of the Jesuits with the Indians because most of this sect were more or less medically trained, and they found the Indians very receptive to such teaching and quick to adopt better methods of medical treatment. The powerful influence wielded by men of the high character and attainments of La Salle and Hennepin, men whose lives and examples tallied with their preaching was thus fully explained, and very much of our most accurate and truthful statements in regard to the social and medical life of the Indians of North America will be found in the pages of the Jesuit Relations.

Franklin's essay on "The North American Savages" also gives us a very honest and faithful account of them. He says: "Savages we call them because their manners differ from ours, which we think the perfection of civility; they think the same of theirs." Unfortunately with the advent of the white man, smallpox, gonorrhea, scarlet fever, measles, tuberculosis, and other epidemic infections appeared for the first time among the Indians, who quite correctly attributed these scourges to the advent of the white missionaries and traders. Hence, it is that the universal antagonism of missionaries to the medicine men naturally developed, especially since the medicine men in all tribes have exerted a powerful influence over their people not only in matters of disease and medical practice, but also in general social and political life, in their theology; and in most tribes the medical men have been also leaders in war; in many instances either associate or chiefs during all times of hostilities. Many of our most famous Indians were of this class, Tecumseh, Sitting Bull, Chief Joseph, Geronimo, and many others.

In most tribes, especially with those of higher types of civilization, the medicine men were selected from the more outstanding, pious, and studious men of the tribe, sometimes, however, because they had passed through some remarkable experience or training. In other tribes, as among us, any person might assert his abilities and if he was able to develop a following he was allowed to do so, but in most instances the aspirant for medicine man was required to pass through a long and severe course of study or training under the auspices of some older and credited preceptor. In certain tribes the office was hereditary and young boys were put under strict training almost from their birth. In a good many instances likely boys were selected by the medical clan and trained by the older and more experienced men for their important office.

In most instances theology has been combined with the practice of medicine and the medicine men have attended or supervised the religious and sac-

ramental ceremonies as well as being charged with the care of the sick and injured. In some of the more highly evolved tribes the priestly and medical functions were, however, entirely disassociated. In almost all instances specialties were practiced; men especially skilled in the treatment of the sick were differentiated from those who attended to surgical disease, for example. In most tribes obstetric practice was usually limited to women, and many of the better tribes recognized both men and women as medical practitioners, in which case consultations and combined practice was usually in vogue. Women, however, rarely took part in war councils or in actual warfare while the medicine men almost without exception did, and as a general rule they were expected to act with particular valiancy and courage, because of their standing in the political, intellectual and governmental phases of tribal life.

My chief experiences with Indian practitioners as it happens, has been with the Ojibway people. For five consecutive years it was my happy privilege to spend a time each fall with the son of one of the most distinguished medicine women of this fine tribe, and through this relationship I was able to come into rather more intimate contact with the people than would otherwise have been the case. This tribe had, and to some extent still has, a most complete organization of its medicine men and women, for in this advanced people, women, properly trained and accredited were also admitted to the medicine clan, the Midi or Midiwin. Happily also the medical clan of this tribe has been most carefully studied by competent ethnologists and probably the medical organization of this tribe has been more completely studied and detailed than that of any other tribe in existence. (Read book of Diamond Jeness.) Two women of this tribe and clan, Mary Bear and Mrs. Steve L'Africaine, wife of a local Hudsons Bay Company chief factor, became quite friendly with me, and through them I met other members of the Mediwin Society. The deep respect in which I came to hold these people has inevitably tintured my attitude toward the Indian medicine man, a feeling but intensified by my less extensive experience with other tribes.

I shall attempt to give a garbled and very much abbreviated account of the organization of this society, largely gathered from reports and studies published by the American Bureau of Ethnology concerning the organization of the Midiwin.

The tenets of this society still permeate the Ojibway tribes and much of their medical practices are still derived from the society which is inextricably intertwined with the religion of this tribe.

Concerning these practices La Hontan (*New Voyages to North America*, London, 1703) says: "When they are sick they drink only broth, and eat sparingly and if they have the good luck to fall asleep, they think themselves cured. They assert that sleeping and sweating will cure the most stubborn diseases in the world. When they are ill they are visited by a sort of quacks, Jongleurs." Hennepin, in *A Continuation of the New Discovery*, speaks of these medicine men in a very resentful and critical manner. Marquette on the contrary, after referring to the Indian Herbs list and in mention of the calumet dance says: "They have Physicians among them, toward whom they are very

liberal when they are sick, thinking that the Operation of the Remedies they take is proportionate to the presents they make unto those who have prescribed them."

The symbol of the Fourth Degree of the Midiwin is the cross, and when Father Marquette found this he considered it as a compliment either to him or to his religion whereas it was but the symbol of one of the degrees of the Midiwin. In addition to the Midiwin these same Algonquin tribes have two other classes of priests or dealers in mystery, the Jessakkid and the Wabeno. These may or may not be members of the medical society, but their functions are quite distinct from those of the real practitioners who were members of the Midiwin almost without exception, except for certain general practitioners, as we would say of domestic or household medicine.

The Jessakkid is rated as a seer and prophet; the Wabeno is prompted by dreams and visions; he is a magician, indulges in exorcisms, etc. He may perhaps be rated in comparison to the regular practitioner of the Midiwin as the psychoanalyst is to us. The Jessakkid brings on evils and spells.

The existence of the society of the Midi is first cited by the Jesuit Relations about 1642. Probably the most understanding account of it, though confessedly very incomplete was published by an educated Ojibway, a member of the legislature of Minnesota, who also wrote the *History of the Ojibway Nation*. Warren states that even with his membership in the tribe, his perfect command of the language and his well recognized friendliness to his people, he was unable to secure absolutely authentic information as to the society, though Schoolcraft claimed to have been admitted as a member; if so he was probably the only white man who ever gained admission to the lodge; and Schoolcraft is quite generally thought to have been, to put it mildly, more picturesque than accurate in his statements.

Warren stated that the traditions and ceremonies of the society were not only transmitted by word of mouth but also by hieroglyphics and charts of ceremonies and procedures. These have of course now been largely lost or contaminated by admixture with the teachings of the missionaries of various sorts, by inattention and the lack of respect paid to the old men and their teachings by the younger generations.

The Rev. Peter Jones who was an educated Ojibway, serving as an Episcopal missionary, in his book (*History of the Ojibway Indians*, London, 1843) states that "each tribe has its medicine men and women, an order of priesthood consulted and employed in all times of sickness. These powwows are persons who are believed to have performed extraordinary cures, either by the applications of roots or by incantations. When an Indian wishes to be initiated into the order of the powwow, in the first place he pays a large fee to the faculty. He is then taken into the woods, where he is taught the names and virtues of the various useful plants; next he is instructed how to chant the medicine song and how to pray, which prayer is a vain repetition offered up to the Master of Life or to some munedoo whom the afflicted imagine they have offended."

Entrance to the society is obtained by a candidate applying to a member with whom he discusses the matter. If the application is favorably considered

it is then discussed with several members of the order, and in case of a favorable decision an instructor or preceptor is designated to whom he must present himself and make an agreement as to the conditions of his instruction, his fees, etc. The whole time of the student is at first not taken up and he has opportunity for hunting, fishing, and the maintenance of himself and his family. He may spend thus several years of study and preparation.

The society is graded into four degrees or periods of instruction.

The garbing of the practitioner differed according to the number of degrees which he had received in the society. Thus in the painting of the face, while acting officially:

First Degree: A broad stripe of green across the forehead and a narrow band of vermilion across the face, just below the eyes.

Second Degree: A narrow stripe of vermilion across the temples, the eyelids and the root of the nose, a short distance above which is a similar stripe of green, then another of vermilion, and above this again one of green.

Third Degree: Red and white spots are daubed all over the face, the spots of the size of the finger tips in applying the colors.

Fourth Degree: Two forms of decoration were permissible; the face was painted vermilion, with a stripe of green extending diagonally across it from the upper part of the left temporal region to the lower part of the right cheek; for the second, the face was painted red with two short, horizontal parallel bars of green across the forehead. Either of these was also employed as a sign of mourning by one whose son had been intended for the priesthood of the *Midiwin*.

The initiation of a qualified candidate into any of these orders was attended with very elaborate ceremonials and dignities, the recital of the history of the degree and clan. The ceremonies were usually if not always preceded by the ceremonial smoking of the pipe, and the Gods and progenitors of the degree were supposed to be invited and present usually in the form of some animal or totem believed to represent each deity or spirit. Initiation was usually celebrated during the latter part of the summer. Some at least of the ceremonies were performed in public so that the people might be duly impressed with their sacred, dignified and important nature. The main ceremonies were celebrated in a "Grand Medicine Lodge" built in an open grove or clearing, but the ritual was unintelligible to all save the initiated. The candidate was required to accurately memorize the ceremonial ritual and to transmit it in time to others, but charts were written, usually in picture writing on birch bark or skins, many of which have been preserved and studied by many students of the subject. These charts appear to me most difficult to make out or translate even with the key at hand, and of course many different interpretations have resulted.

Tobacco and other presents were furnished by the candidate, but charitable or devout members of the tribe, not participating directly were permitted to furnish gifts or contributions to the banquet and celebrations. The officiating priests were well remunerated. A specific preceptor or "docent"

was delegated to each candidate. The drums used in the ceremony were particularly constructed and consecrated. Naturally the occasions when so much highly charged "Good Medicine" was about was supposed to be particularly beneficial for the sick of the community who were expected to add of their wealth to the sacredness and dignity of the affair. Special rattles were used and the Migis, a small white shell of particularly mystical and sacred nature was extensively employed, particularly in the "Shooting of the Migis" in which the celebrant shot the spirit with the shell into the body and soul of the candidate, and the body of the sick attending the clinic. A certain amount of originality was evidently permitted the celebrants and the practitioner was allowed personal deviations as expressing his own peculiar power. The Migis shell was the sacred emblem of the society in general.

Midi Therapeutics.—During the considerable period of time in which the candidate was being instructed in the traditions, myths, songs, and ceremonies, the Midi plants were also discussed and the methods of identification, preparation, and administration of the therapeutic agents were elaborated. Specific agents and plants for definite complaints were discussed. The recognition of the complaints was necessarily mostly founded on symptoms, not on etiologic factors for little was known of this; for most, if not all diseases were believed to be of mysterious, divine, or devilish origin. In this regard it is highly probable that much of real value was further derived from the Catholic Fathers who for the time were fairly well versed in the medicine of the day; therapeutic effect was almost always attributed to the eviction of a bad spirit of some sort, and the efficiency of any method was supposed to be based on the superior knowledge or more powerful medicine of the celebrant. This did not, however, pertain to traumatic surgery in which the relation between cause and effect was fully recognized and acted upon; hence the surgery practiced was as a rule very intelligently based, and the treatments of dislocations, fractures, contusions and wounds was almost always very effectively carried out. They were skilled in massage, and in the application of active and passive movements.

Purification of the candidate was effected primarily by the sweat bath or ceremony, sometimes by the administration of cathartics and emetics. During these ceremonies the candidate was supposed to fix his mind on high and good things; he was fumigated by smoke, remained under certain taboos, as abstention from women and the like. Menstruating women were particularly supposed to injure the effectiveness and sanctity of any of these ceremonies.

In the conclusive stages mystical feats of legerdemain, sleight-of-hand, and the like to index the mystery and control which the medicine of the priests and candidates possessed. Many clever tricks were performed and just as among modern magicians the audience was not instructed as to the manner in which these seeming miracles were accomplished. Certain intimate ceremonies and instructions were carried out in private, in closed lodges and the like.

After the initiation proper had been accomplished the newly elected candidate proceeded to show his power and magic in shooting the Migis, produc-

ing syncope in his confreres, etc. The bear is a sort of tutelary spirit, the "Manido" of the society and enters largely into the mystical ceremonies.

Initiated practitioners might individually purchase from other members special songs, ceremonies, or methods which were supposed to be of particular merit; this was done outside the regular initiation ceremonies, but in the acquiring of a further degree he must gather together sufficient wealth and presents with which to endow the members of that degree. Thus certain practitioners may lead others to feel that he has a special medicine or mystery which enables the hunter to be particularly successful, to enable the lovelorn to bewitch his beloved and the like. In short, voodoo magic is quite well exemplified in many of the particular methods. Some of this "medicine" was doubtless of real value. Shrewd men of close observation of the habits of certain animals were able to impart for instance to the ambitious hunter information as to the taking of game, and the like which was the result of real keen study; most of it was probably just as valuable as the love spells and magic formulas which our young people still pay well for. A medicine man for example may from conversation with many hunters, from men of other tribes acquire a wide and valuable information as to hunting grounds, migration of animals, the methods of setting traps, and the like.

Many women took the degree of the Midiwin, but for the greater part their practice was restricted to women and children, but by no means always, if the modern practice which I have seen among the Ojibway is illustrative.

It is perhaps unnecessary to go into the details of initiation, into the various four degrees; it was largely a matter of the price and of the adeptness and personal character of the candidate. Initiation into the second degree cost twice as much as that to the first; the third degree three times; and the fourth and last degree four times as much. The "Grand Medicine Lodge" differed materially in each of the four degrees, just as it does in the conferring of the various degrees of our fraternal orders. Each degree had a chief priest, usually the senior, and on his death he was replaced by the election of a successor.

The amount of influence wielded by the Midi was general and immense, and particularly that of those who had taken the four degrees. They were believed to stand nearest to the great spirit and all the gods. A Midi Wabeno was also much dreaded because of his supposed supernatural powers.

The greatest just criticism which has been leveled against the Indian Medicine man has been because in most instances, except in traumatic surgery, which naturally played a very large part in Indian practice, of the mingled religious ceremonies with his practice; yet I have heard prayers for the sick offered up in nearly all churches and the various modern sects of our Christian faiths. Having witnessed both, I fail to find in the service of our modern faiths anything more dignified, beautiful, and worshipful than some of the chants or "dances" of the red man, conducted for the benefit of the sick, or for the purpose of imploring the assistance of their divine being in the welfare of their people. It must indeed be a very supercilious person who can fail to realize the sincerity and true devotional aspect manifested even today

in many of these ceremonies. The red man has never descended to the absurdities of Christian "Science," nor has he ever accepted anything more unscientific than the teachings of the osteopaths, chiropractors and the like, practices which are accepted by many of our wealthy, educated, and leading people. I do not believe that any flirtatious Indian girl was ever able to get away with such a story as that of Leda, of the cultured Greeks.

I feel then that we can well afford to ignore whatever of charlatanism, insincerity and faking which took place in association with Indian medical practice, since we ourselves are daily guilty of the same practices, in the universal seeking for the assistance of the mysterious, occult or religious, especially when we or ours are gravely ill. Time does not permit me to enter into this phase of medical practice or Shamanism, except to point out that our people of today practice exactly the same methods, though perhaps in a different form.

Suggestive therapeutics played a very important rôle in the practice of red medicine, just as most of us employ the same methods daily in our offices and hospitals. Many Indians were adept in the practice of hypnotism, and they employed this strange power exactly as we do today in our best psychiatric clinics. Certainly their understanding of this power was no less than that of the highly intelligent, scientifically trained Dr. Mesmer who was one of the greatest scientists of his time.

Time does not permit us to go into the matter of these ceremonies to any considerable extent, but we cannot leave this phase of our subject without reference to the Medicine Lodge and the important rôle which it plays both as a devotional observation and as a method of medical practice in practically all tribes.

The Medicine Lodge was a term commonly applied to a structure erected strictly according to many solemn ceremonies, designed to propitiate an angered or careless God or to express the spirit of humiliation, thanksgiving, or supplication, either on the part of a person or a people.

It was constructed on occasions of momentous national affairs when the whole tribe or tribes were gathered together for the purpose of council, because of some great public or personal calamity, epidemic sickness, or because of some personal complaint of so grave a nature that it was not felt that ordinary or usual priestly or medical ministration was sufficiently weighty. Even when the lodge had been built and the people and its priests gathered for the purpose of discussing some tribal or national matter, as the advisability of going to war for example, it was felt that the moment and the place was propitious for the treatment of any private physical ill.

Persons of great piety, wealth, or who, because of some personal blessing, illness, or misfortune or vow, wished to undergo the necessary expense attendant upon the building of a medicine lodge might undertake it, of course under the guidance and instruction of the chief medicine man.

Having been constructed according to the ritual, certain ceremonies, depending on the purpose of the lodge, were then performed by the medicine men after which the real object of the ceremony was reached, whether it was a council of war or for the treatment of some sick person.

Almost invariably, because of the universal employment of the sweat, either in religious or for purely medical purposes, the building of the medicine lodge was accompanied or preceded by the building of a sweat lodge, sometimes a large structure accommodating several celebrants, or a smaller one designed for but a single person at a time. At times the ceremony of sweat seems to have been carried on in the large structure, that is, in the real medicine lodge, but it appears to have been more usual that those who had been first prepared by the sweat were admitted to the ceremonials in the great lodge.

As an example of the type of chant or litany which was employed in the course of the treatment of diseases, I wish to quote the Sacred medicine formula of the Cherokees, employed by Gahuni, a famous medicine man of that tribe, in rheumatism known as "The Crippler." Gahuni died about 1855. I shall allow you to judge if it is more foolish than the mumbo of the successful quacks of today. (Seventh Annual Report, Bureau of Ethnology, 1885-86.)

"Yu! O Red Woman, you have caused it. You have put the intruder under him. Ha! Now you have come from the Sun Land. You have brought the small red seats, with your feet resting upon them. Ha! Now they have swiftly moved away from you. Relief is accomplished. Let it not be for one night alone. Let the relief come at once."

"Repeat this prayer four times. (If a woman you must say 'Red Man' and if a man, you must say 'Red Woman.') Meanwhile laying on hands, take off the hands; blow once at the fourth repetition, blow four times. And this is the medicine. Egluni (a fern), Yat na-Utsesta (Christmas fern), Ka ga Asgutage (Maiden hair fern), Da yi-Unwayi (Beavers paw). Boil the roots of six varieties together and apply the hands warm with the medicine upon them. Doctor in the evening. Doctor four consecutive nights. (The pay) is cloth and moccasins, or if he does not have them, just a little dressed deer skin and some cloth."

And this is the tabu for seven nights. "One must not touch a squirrel, a dog, a cat, mountain trout, or women. If one is treating a married man, he must not touch his wife for four nights. And he must sit on a seat by himself for four nights, and must not sit on the other seats for four nights."

Religion is always a difficult subject to discuss dispassionately. The Indian had his religion, and whatever his beliefs, he took it quite as seriously and much more faithfully than most of us do. My own private belief is that he is quite as much entitled to his beliefs as we are to ours. Whatever of brutality he may have shown has been quite equalled by many of those who profess the faith of the gentle Jew of Nazareth. As in the early days of our own medicine, religion has also been intimately mixed with the medical practices of the Indian, and this is the chief criticism which we may level against it. Psychotherapy, however, is a very important agency for cure in many, if not most diseases, and the red man has realized this perhaps more fully than we of this age do. As has been recently said by one of our leaders (Thomas Salmon), "No medical system can be complete and fully satisfactory until the proper commingling of psychotherapy with the methods of real science of pathology, chemistry, and bacteriology has been found." Until we medicine men of today have properly realized and adopted this fact, we are in no position to criticize the red prac-

titioner who did without question practice this associated psychotherapy and physical practice with notable success and well adapted to the requirements of his patients.

Naturally for an intensely religious people, the theory of disease among practically all tribes is the same, namely that of an evil spirit or bad medicine which has entered the body and caused sickness. Obviously the thing to do in that case is to drive out this evil spirit by a stronger good medicine, for which quite naturally the gods must be appealed to through proper prayers and medicines. Hence, it is that most of the incantations practiced or in vogue are such as the shooting of the Migis of the Ojibway and the sucking out of the disease which is so generally practiced not only by Indians but also by simple whites and even by animals. As is well known the medicine man in such treatments is likely to conceal in his mouth or elsewhere on his person a stone, or perhaps some living object as a cricket, frog, or the like which he dramatically produces at the proper time.

I have known of many whites who also believe in the efficacy of prayer and of divine intervention in cases of sickness. Perhaps we all are somewhat inclined in this direction to a greater or lesser degree, so why laugh at the Indian? Our church services seem quite as absurd to him, so I am told, as his ceremonies do to us.

Of course the shaman performance opens the ceremonies of the Indian to the ridicule which the superior white is likely to visit upon it, and the whole thing is then considered as a bit of charlatanism. I do not, however, agree with this conception for I am convinced that in many instances at least, the removal of the foreign body on the part of the priest has precisely the same significance as the very similar ceremonies practiced by our shamens. The attempt to deceive and willful faking is not in the mind of the respectable practitioner any more than it is in the mind of our psychiatrists when they do practically the same thing in their practice. Those of you who have seen these treatments given, cannot I am sure, have failed to note the reverential attitude with which it is usually conducted. The psychic benefit to the patient at least is real.

It is, however, a real pleasure to turn from these phases of medical practice to the methods of the Indian which commands our respect as scientists and as modern physicians.

Long before the days of Hippocrates, of Paracelsus, long before Koch, Ehrlich and Pasteur, the Indian medicine man practiced an art which came close to a science which even today commands our utmost respect and emulation.

Before Egypt was a nation, long, long before the dominance of the Greek school, Verrill with others, has shown us that the Indian medicine man practiced successfully Cesarean section, symphysiotomy; he understood and applied the wide use of trephining; he unquestionably used cocaine as an anesthetic together with other effective sedatives and analgesics; he installed dental plates and bridgework; he even supplied his patients with artificial limbs.

The writings of practically all our army surgeons shows that even the Indians of the days of Custer, Crook, and Miles well understood the treatment of fractures, dislocations, of stab and arrow wounds, and his treatment of gun-

shot wounds in the more intelligent tribes was efficient and in many respects admirable. I myself have seen something of this surgical practice. I have seen the most clever sort of splinting in fractures; I have seen ball and stab wounds well treated, the lips of bulging or gaping wounds cleverly approximated, and others have reported the use of thorns and skewers for this purpose. Shrewd and hard-headed men such as Alaes Hrdlieka, himself a skilled physician as well as one of our most eminent ethnologists and anthropologists, has spoken frequently in unstinted praise of some of these methods of surgical treatment. I have also observed as a youth much of the efficiency of pioneer medicine which owed its origin mostly to the red medicine man.

I have heard my own parents speak in terms of affection and respect of the work of Old Baptise, medicine man of the Sioux whose services were so respected and valued by the white settlers of Minnesota that when his tribe was sent to a reservation, he was asked to remain, supported by the government because of his value to the early settlements of Minnesota. I cannot say that many of the doses of "simples" which I received as a child were loved at the time by me but at least we grew up to be as healthy, sane and sound as the men and women of more advanced communities. Whatever may be said against Indian Medicine, it was also that of the pioneer in very large degree. The reports of army officers, particularly of medical officers is almost universally respectful of some at least, of the medical customs of the Indian. Furthermore almost without exception explorers, miners, settlers, and those others who have lived among the Indians have universally cited frequent instances in which strikingly successful treatments have been given by these primitive practitioners. I am certain that few of us who were born of pioneer stock or who have lived among even the modern tribes hold anything but respect for what we have seen and experienced of Red Medicine. Verrill cites, for example, his successful and comfortable recovery from yellow fever under the care of medicine men.

Let us then consider in some detail certain of the drug uses and other practices for which we are entirely dependent upon the Indian. I shall pass over these drugs very briefly, for I am confident that most of you know the more important of them. Perhaps we should put at the head of this notable list, quinine because of the great rôle which it has played not only in individual medical practice, but also because without quinine the march of civilization, great engineering and military projects must have been halted or become entirely impossible. Cocoa, with its derivative cocaine which has become so universally employed in many branches of medicine, we also owe entirely to the South American Indian. Cascara is also of Indian origin. There are many others peculiar to Indian origin, but usually in less frequent general recognition by our present-day profession. As for drugs which are universally employed, and the direct origin of which no man knows, they are very numerous. Saline laxatives were widely employed in practically all districts where nature supplied them; we might say the same for most of the wild animals also, as every field hunter knows. Foxglove, a crude form of digitalis, was widely employed in the districts where it grows. The list of laxative drugs used by the Indian is very large, and from personal experience, I can definitely say

that they are highly effective. Diuretics also are very numerous and highly efficient; mostly they are decoctions of various plants, and commonly they are administered in warm or hot water, which of course greatly increases their effect.

Emetics, now rather infrequently employed in our practice were and still are very extensively used by the Indians. Under many circumstances they were employed for religious purposes, as for example in the course of the preparation of the celebrants of the snake dance, but they are also very generally used in any manner of gastrointestinal disturbance much as we use laxatives in very many disorders, empirically. There is a tremendously large list of drugs used for the purpose of emetecesis, including large quantities of warm water and irritation of the fauces, after our own manner. Decoctions in warm water of holly, cucumber, thoroughwort, blood root, etc., ad infinitum. Among the Navaho the fermented urine of cayuses is used, and I am informed by an Indian trader, quite familiar with the Snake Dance ceremony, that the fermented urine of the burro is usually employed in this ceremony, supposedly because it has also some antitoxic effect against the bite of the rattlesnake.

I have found it extremely difficult to get accurate information from my Indian friends, even when they were entirely convinced of my sincerity. They are as a class very sensitive, fearful of ridicule, and most evasive in their answers to questions. I have found my most successful avenue of approach to speak as a member of the same general medical fraternity, seeking from them further information, usually telling them what I did in certain cases and asking in turn what they would do under similar circumstances. Occasionally I have been able to establish thereby a quite satisfactory relationship, but I am fully convinced that most intelligent medicine men also employ a good many valuable drugs of which we know nothing, and I am certain that scientific study of some of their preparations would be of great benefit to us. Many explorers and ethnologists have made this statement to me also.

It is quite natural that the Indian should be skilled in meeting particularly the conditions which he contacts in his ordinary life. This is shown especially in his management of snake bite. There are of course several varieties of snakes whose bite is invariably, or practically always, fatal. Against some of these reptiles they have no antidote, but I am informed by field ethnologists, explorers, miners, and the like that they are certainly able to successfully treat the bites of many supposedly highly virulent forms of snake bite. Not infrequently whites exposed to this peril have profited by this knowledge, but I have never known an Indian to divulge this secret.

The trader at Oribe who had been among the Pueblo people many years told me that he had never seen a case of fatal snake bite among those tribes to whom the snake is sacred, and yet who handle them frequently and are often bitten by them, ill-protected as they are by scanty clothing. In the famous snake dance, this same man told me that he had never known serious illness to follow the bites incurred in this ceremony although bites from the western rattler are very frequent in the chant. Of course this has been in part accounted for by the fact that for several days preceding the dance the snakes are very much disturbed and the probability is that their poison is largely exhausted by the

time of the actual ceremony. Still it is certain that of the several preparations taken before the dance, in the purification ceremonies, that antidotes are taken, whether with success or not cannot be determined. During the emetemsis which precedes the dance, the urine of the burro is taken in large quantities because of its emetic effect, and it is supposed by some that this acts also as a protective. They very generally in case of bites from poisonous reptiles, practice as we do, scarification and local blood letting, and this doubtless helps some, but face, neck, and arm bites are common during the dance. At least the dancer goes on with his ceremony with apparent indifference. The Indian bystanders, not participants, are certainly quite as adverse to the snakes as we are. I think that we must conclude that they do have protective measures of which we know nothing.

Febrifuges are in common use. dogwood for example, which contains cinchona in considerable quantities is so used in decoctions. My Yanqui guides in Durango, Mexico, used infusions of sarsaparilla among other preparations for this purpose, and I know from personal experience that they are effective in considerable degree.

Astringent decoctions, abstention from food, and rest are widely and successfully used in diarrhea. My Ojibway friends used a decoction of spruce or oak root for this purpose. I think each tribe has useful preparations for this purpose, depending, of course, on the plants or drugs available. My mother used fermented decoctions of wild blackberry, for example, for this purpose, and I recall that when I went away to study medicine my mother provided me with a liberal supply of this, which she had, as a pioneer woman, learned to use. It was not only effective but also very pleasant, particularly when it had sufficiently fermented. On several trips my Indian guides have supplied us with very effective preparations of like effect; but it is exceedingly difficult to get them to tell what these preparations were, notwithstanding the fact that they were certainly most kindly inclined toward me.

Very much has been said as to the immunity of Indian women from the ills peculiar to our women, of their quick and easy labors, immunity from perineal tears and the like. So far as the recent Indian is concerned, I think that these statements are incorrectly based. It is true that most Indian women do get about immediately after labor; it is also true that they very frequently have very severe obstetric difficulties as do our women. It is very true that they are stoical and indifferent to pain, for that is the custom of the people who are not given to emotional demonstrations of this kind, but from my conversations with agency doctors and from my contacts with the Indians, I am certain that they are quite as liable to difficulties of this kind as the same social types among white women, that is as compared with pioneer women, farm women and the like, but of course not comparable with women who are soft of muscle, overly fastidious, and the like. I have seen plenty of Indian women who suffered extremely from dysmenorrhea, menorrhagia, and similar conditions. I do think from my own observation and from the statements of reservation physicians that fibroma and myomas are much less frequent among them than with us. I well remember overtaking a party of Ojibway friends encamped on their way to the hunting fields because they did not wish to leave behind a favorite daughter of the chief,

who was suffering from dysmenorrhea and menorrhagia. They were as anxious as I was to get on to their hunt, but the chief told me that women were a great hindrance to tribal activities because of the troubles incident to their sex.

Malignant growths are certainly very much less frequent among the Indians than among whites. In fact they are rare among the unmixed tribes. I have never seen a malignant growth in a pure blood Indian, and reservation doctors report to me the same; it is also remarked upon by Hrdlieka. I looked into this matter last year while in Mexico, where the population is preponderately Indian. In many places tribes, like the Yaqui, have preserved to a marked degree their racial purity. Every physician with whom I came in contact made the same statement that malignant growths were exceedingly rare among the Mexican Indians. Dr. Palomecque, a young and exceedingly brilliant surgeon, had practiced two years in the city without seeing a single instance of gastrointestinal carcinoma in an Indian, though he had a large public charity practice. Dr. Ramon Molina, probably the leading internist of Mexico City also confirmed the same statement; and among the other physicians, including a leading pathologist, the same opinion was voiced. Hence it is that there appears to be very little knowledge among the Indians concerning newgrowths. They are certainly very rare, as is also true among pure strains of wild animals. Mr. Fenley Hunter of the Explorers Club has recently reported to me the death of a well-known squaw, Big Mary of carcinoma at Fort Yukon. The diagnosis was conformed by Dr. Hrdlieka.

The same appears to be true of thyroid disease, though I have seen simple nontoxic goiter in Indians living in the so-called thyroid districts.

Naturally rheumatism is one of the most serious diseases with which the northern tribes have to contend, the Ojibways, the Crees, and the northern tribes in general. I believe that it is rarely seen in the south, among the Pueblos, the Navahos, the Mayas, and so on. Naturally in those peoples greatly afflicted with this disease with its high disabling effect, treatments are very numerous. Perhaps in this respect they practice polypharmacy as liberally as we do in the same condition. Hot applications, the inevitable sweat bath, demulcent drinks and many decoctions are widely employed, and certain tribes use willow bark and twigs in the form of a decoction. Among the Midiwin practitioners the willow ash, which is, of course, high in the salicylates is extensively employed. I was shown its preparation by a very fine old gentleman, one of the Midiwin society of the Ojibway. This man was not only highly intelligent, but a real gentleman, if acts outweigh clothing; and he was also a most artistic and ingenious builder of the birch bark canoe, now practically obsolete. Massage, active and passive movements were employed extensively both in this disease and also in the treatment of sprains, bruises, and so on.

Anodynes and anesthetics were doubtless more extensively used and elaborated by the South American tribes, the Pre-Incas and Incas, Colimas, etc. It must always be remembered that in these sections, particularly about Lake Titicaca, an order of civilization existed which beyond doubt exceeded that of any other human race at the time of its zenith, and in many respects this persisted, though in a degenerated type, up to the time of the Spanish conquests. But our story has chiefly to do with the Indians of the times of our forefathers.

Stramonium of several kinds was used rather extensively both to quiet pain and also to produce a condition of semiintoxication in certain ceremonies. Even up to recently the government has attempted to prohibit the use of the peyote, which induced a condition of intoxication, comparable to the use of opium. Aleoholies were and still are in extensive use among the Indians of Mexico, in the form of mescal, and the favorite present-day drink in Mexico is pulque. Both these drinks, unless most artfully disguised, taste most terribly to the unaccustomed palate, but the last mentioned forms a considerable article of the diet of the ordinary Mexican. The northern tribes as a class used aleoholies very little. These preparations were very extensively employed by the tribes familiar with them, in various nervous conditions, for mental and nervous diseases were familiar enough in Indian Society. I have seen as characteristic and striking hysterical attacks among young Indians as one might wish for. As I have previously mentioned, among the members of the Midiwin, the shamans who undertook the treatment of neurologic diseases were rated in the last or highest chapter of their "Grand Medical Society." As has been noted by very many writers, mental disease was rated among the plains tribes in general as being related to the Great Spirit. These sufferers were judged as to a considerable extent irresponsible, or under the special care of the Great Mystery; hence they were treated with great kindness and consideration, a fact which was utilized, we are told, with advantage by prisoners falling into the hands of these tribes. At least we must consent that such a method of management was considerably in advance of the treatments for the insane, prevalent almost up to the time of Chareot among some Christian peoples. Our amiable ancestors of New Bedford and Salem might have taken a beneficial lesson from the red barbarians.

Treatment of contagious diseases was very badly carried out as a rule, and it is probable that in most cases it was harmful rather than otherwise, since the sweat lodge and cold plunge apparently represented the most prevalent method. It must, however, be remembered that apparently most of the epidemic contagions were introduced by the white man, typhoid fever, smallpox, measles, scarlet fever, diphtheria, and the like. Probably the less said about these matters, the better. It is quite certain, as I have said, that nearly all of these contagions whether treated by medicine men or agency physicians are terribly fatal; whole tribes within my memory have been almost wiped out by measles, for example. Darwin mentions this fact in his *Voyage of the Beagle* and even at that early day, he made a correct interpretation of its significance; for he remembered that this great scientist had been a medical student, and that he never lost his interest in medical science.

Venereal diseases were very prevalent following the early contacts with the whites. They were for the greater part very poorly treated. This was the result of overly generous social customs, frequently mentioned for example in the voyage of Lewis and Clark. It has been told me by several well-qualified men that the southern tribes in Mexico have a plant, the Yerba Santa which is effective in syphilis. There is no doubt, I think, but that the Indian has now acquired an immunity against syphilis which is higher than that of most whites, but syphilis acquired from such infected tribes is likely to run a very malignant

course when acquired by the whites. Hrdlicka asserts with authority that there is no evidence of pre-Columbian syphilis, though the disease syphilis was spoken of variously as the "Mandan Disease," the "Gros Ventre Disease," and so on from its supposed origin from the Indian.

The subject on which I have ventured to speak to you is a most interesting one; it has pleasantly occupied much of my spare time, and has given an added interest to my trips into the wilds ever since my boyhood days. I am certain that future study of the medical customs, especially of the South American tribes and of certain of their drugs will certainly add to our armamentarium other drugs, perhaps as valuable as quinine and cocaine. The late Dr. Rusby, known to all of us for his researches along these lines frequently made this statement. Doubtless when the archeologists have found the key to the inscriptions of the Tiahunacans, the Preineas and the Incas, the Mayas and Toltees, we shall find further evidence on medical matters of great value to the world, just as artists, sculptors, architects, economists, and students of government await anxiously positive accounts of the wonderful people who preceded us on this continent.

We may at least be certain that the medical practitioners of these people have played an important and honorable rôle in the early history of America; one which reflects honor on us who have followed them in the study and practice of the healing art. It is certainly regrettable that we have long been so blind to the great part which the prehistoric physician of America has played, and that we are still so prone to feel that in the history of progress in art, architecture, mathematics, astronomy, and even in government, we owe most to the old world while the sciences of archeology and ethnology have definitely now shown to be not in advance, but behind the early civilization of the Americas.

In my talks on this fascinating subject, I have been frequently asked for references to literature on the subject. In the hope that you may find as much pleasure and benefit in the study of this subject as I have, may I refer you first to the numerous publications of the Department of Ethnology. Get as many of the old volumes as you are fortunate enough to be able to procure. Have at hand the Encyclopedia of the American Indian. It is now old, and does not include recent discoveries, but it is most interesting none the less.* Read Schoolcraft, though he was a picturesque liar; read and study the egotistic inaccurate but fascinating and courageous story of Catlin; his plates are none the less our first artistic data on the life of the American Indian of the days of our grandfathers. Read and reread Lewis and Clark, particularly the edition of Dr. Elliot Cowes. Read Colden's *Indians*, Colonel Dodge's *The American Indian*. Read the early publications of Lieutenant Bourke. Do not forget the valuable material to be found in the Jesuit Relations, the tale of Father DeSmet; read and marvel at the story of the courageous Cabeza De Vaca, of Coronado, of Pizarro—and when your palate tires of detective stories, read the diary of Bernald Diez del Castillo, the Lieutenant of Cortez. Do not forget Prescott's *Conquest of Mexico*, or his charming story of the *Conquest of Peru*.

Read the carefully compiled volume on *Shamanism* of Dr. Maddox. Gather to your choicest volumes everything original that you can find on early American history, and the records of the colonists both of our own United States and of

*A new edition is now under way.

Canada. Read Franklin's *Essay on the American Indian*; Cotton Mather. Read Schultz's *My Life as an Indian*; read every book that you can lay your hands on written by Verrill; I believe that there are only seventy-nine volumes as yet. Read the publications of Dr. Alaes Hrdlicka, the charming volume of Dr. Hough *The Hopi*. Everything written by Clark Wissler is beautifully done and most authoritative. All the publications of the American Museum on the subject are well worthy of their origin. There is a very fine little volume, recently written by Dr. Erie Stone in the series, *Clio Medica*, on *Medicine Among the American Indian*. Better still visit and revisit the marvelous collections of the Museum of the American Indian, Heye Foundation, the American Museum of Natural History, the choice though small, and local collection in the City Museum of Milwaukee; and you will soon find yourself equipped with a most fascinating hobby which will bring you pleasure and profit just as long as your cerebral cortex is intact. Your library will grow by leaps and bounds; you will haunt the old book stalls, and your spare change will not go to Wall Street.

Best of all, visit the Mesa Verde, Pueblo Bonito, Kitseal, Betata Kin, the still active Indian villages of Zuni, Oribi, Walpi, and the pueblo towns in general of New Mexico and of Old Mexico. Marvel in Mitla, Mont Alban, the City of Mexico with its unequalled collections and its dramatic history and startling views. And there is still Yucatan, with its preposterous and beautiful old cities, older than Egypt. There still remain for you, all of Central and South America with Cusco, Tia Huanaca, and the old Preincan and Incan towns of Peru, Bolivia, Chili—then you have started on a lifetime search of the beautiful and marvelous, on a study of the history of the country where "Columbus Came Late," but where you and I live, in a land with a history and heritage elsewhere unequalled.

FUNCTIONAL STUDIES OF PATIENTS ON ANTIARTHRITIC MEDICATION

DAVID STEIN, M.D., AND WILLIAM C. MINNICH, M.D.
PHILADELPHIA, PA.

THE primary purpose of this study was to observe the functional reaction of unselected arthritics to a few standard types of medication. Accessory modes of treatment which were based upon the etiology, and aimed at curative effect such as the elimination of foci of infection, were carried out in all cases. From the standpoint of this study, however, the latter methods were of academic interest only. The secondary purpose of this study was to observe whether, in a comparatively small series (143 cases) of arthritis, under moderate dosage of common drugs, idiosyncrasy or lack of tolerance by the kidneys or liver was frequent or the reverse.

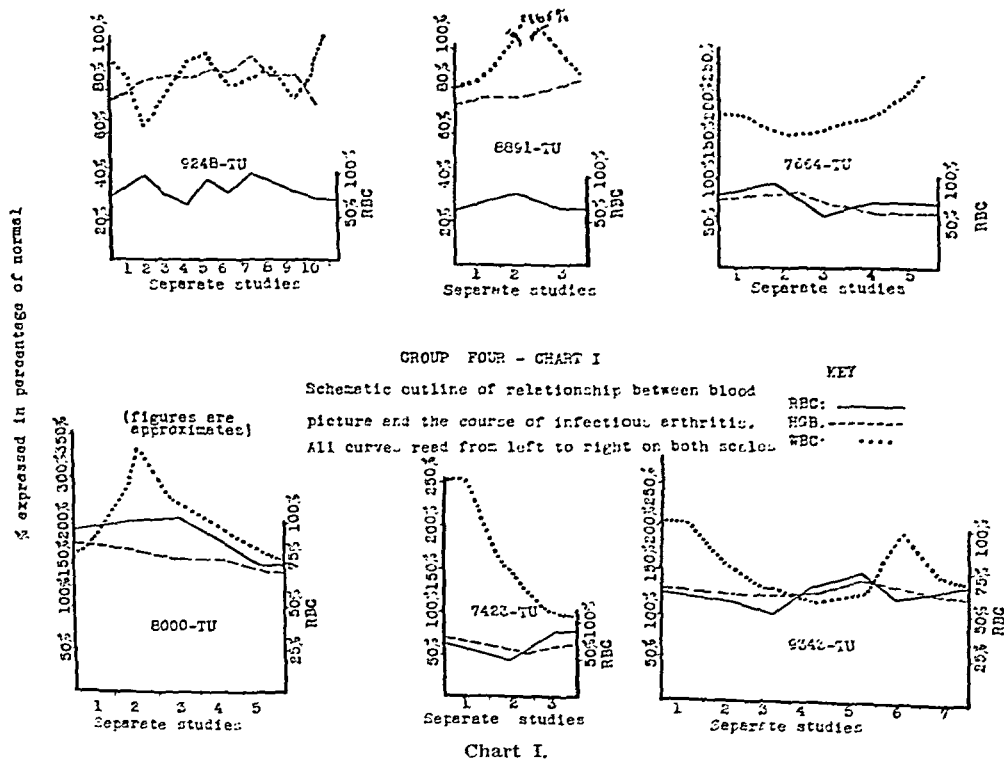

In 1923, Worster-Drought¹ published one of the first alleged cases of phenyleinchoninic toxicity, which recovered. In somewhat desultory fashion other cases, with recovery, were reported for the subsequent three years. In 1926, Langdon-Brown² published one of the first³ reports of a death, due to atophan. From that time to the present, there have been reported several cases of intoxication due to phenyleinchoninates. The authors appear to have overlooked the fact that not only does acute yellow atrophy arise from many causes and many drugs, but that the well-known salicylates have also been known to cause this condition.^{3, 4, 5} Further, authors appear to have failed to compare the annual consumption of phenyleinchoninates and salicylates with the relative frequency of symptoms of intolerance. Since the manufacture of the former runs to almost one hundred thousand pounds, and of the latter to three million pounds† in the United States alone, it must be fairly obvious that the chance of intoxication, statistically, is slight.

There is a large bibliography on these questions of toxicity which it is scarcely necessary to cite. It seems to us that further work in the clinic, coupled with some of the newer laboratory studies, should be done to amplify the findings of the earlier writers such as Hanzlik.²² As to the use of phenyleinchoninic acid (cinchophen) itself in these studies, we were of the opinion that the position taken by the *Journal of the American Medical Association* in 1931 was sound; and that we would, accordingly, not use phenyleinchoninic

*We consider the case reported by Cabot (Boston M. & S. J. 192: 1122, 1925) to be erroneous and so shown by the report in the J. A. M. A. 89: 1167, 1929.

†U. S. Census of Dyes and Synthetic Organic Chemicals: U. S. Tariff Commission, 1930, pp. 60, 61. Manufactured Salicylic acid 2,781,196 pounds, Cinchophen 93,765 pounds.

acid. The statement said (J. A. M. A. 97: 409, 1931): "... it would be well to discontinue the use of cinchophen, or atophan, and to substitute neocinchophen for it. . . . This remarkable safety of neocinchophen is also reflected by the fact that it is practically impossible to find one undoubted case of neocinchophen liver atrophy in the literature." These facts, then, that neocinchophen and the salicylate of sodium have been so very rarely accused, led us to use these drugs in our study. We are in agreement, so far as the clinical side of the picture is concerned, with the conclusions of Davis,⁷ who has recently said: "A study of 200 cases taking neocinchophen or cinchophen has been made. . . . The superiority of neocinchophen to cinchophen for general

clinical use appears, at the present time, a fair conclusion from the evidence of the literature and the author's cases."

In the matter of nomenclature, we have been guided by the *Rheumatism Primer* published by the American Committee for the Control of Rheumatism. As they observe, no classification suits everyone or every case, but a simplified classification aids us in the comparative judgment of reported cases and hence should be adopted where possible.

Our laboratory tests² have been the classical ones as described by Hawk and Bergeim,⁸ Meulengracht (Brown's modification),^{9, 10} van den Bergh,¹¹

²To avoid prolixity we use the quite widely recognized abbreviations of E.K.G. for electrocardiogram; B.S.P. for the bromsulphalein test; and P.S.P. for the phenolsulphonphthalein test.

Bauer,¹² Wallace and Diamond,¹³ Rosenthal and White,¹⁴ Cantarow,¹⁵ Davies,¹⁶ and Rowntree and Geraghty.¹⁷

Blood pressure studies were made on every patient; and on some patients as many as twenty or thirty determinations were made, but we found nothing of the slightest functional significance. Many blood picture studies were made, and the results in a few cases, as regards progress of the infection and secondary anemia, have been shown in Group 4 chart.

The rationale of our procedure is more clear if we consider the cases in an order inverse to the complexity of the findings. One of us (W. C. M.), seeing constantly, in his office, a considerable number of industrial cases, observed clinically, without laboratory study, 70 unselected cases of traumatic arthritis upon minimum medication of one type. The other of us (D. S.) observed similarly, at the various dispensaries to which he was attached and in his office, 50 unselected cases of arthritis, usually infectious, upon another type of medication, in minimum dosage. The first 70 case series was composed as follows:

Arthritis of the:

Feet	8 cases or 11 %
Knee	11 cases or 15½%
Ankle	5 cases or 7 %
Lumbodorsal vertebrae	5 cases or 7 %
Digits	5 cases or 7 %
Pelvis, including the sacroiliac juncture	6 cases or 8½%
Forearm, including the wrist	7 cases or 10 %
Upper arm and shoulders	4 cases or 6½%
Miscellaneous traumata about the muscles, femur, ribs, legs, etc.	19 cases or 27½%

The age distribution of these cases was as follows:

10 to 20 years	1 case
21 to 30 years	15 cases
31 to 40 years	27 cases
41 to 50 years	20 cases
51 to 60 years	6 cases
61 to 70 years	1 case

The sex distribution was: males, 67; females, 3. The youngest patient was eighteen years of age; the eldest, sixty-seven. The average length of treatment was four weeks; the shortest, one week; and the longest, twelve weeks. Every patient received 5 gr. of tolysin* three times a day. The symptomatology was affected as follows:

Moderate relief	19 cases or 27%
Marked relief	49 cases or 70%
No relief	2 cases or 3%

*A brand of paramethylphenylcinchoninic ethyl ester, manufactured by the Calco Chemical Company, Inc.; other names being used in the literature for this chemical are neocinchophen, novatophan, etc.

While laboratory studies were not done upon these patients, none at any time complained of gastrointestinal, hepatic, or renal symptoms, or showed the signs of such organic dysfunction.

In a manner roughly parallel to the above method, 50 ambulatory cases were observed by one of us (D. S.) under minimum medication with elixir sodium salicylate compound (N. F.). They received the equivalent of 5 gr. of sodium salicylate plus potassium iodide, gelsemium, cimicifuga, etc., in an alcoholic medium, three times a day. These unselected office and dispensary cases of arthritis may be anatomically subdivided as follows:

Arthritis of the:

Ankle	7 cases or 14%
Wrist and hand	6 cases or 12%
Elbow	1 case or 2%
Shoulder	6 cases or 12%
Knee	7 cases or 14%
Hip	1 case or 2%
Sacroiliac joints	3 cases or 6%
Several joints	10 cases or 38%

The ages were distributed as follows:

10 to 20 years	3 cases
21 to 30 years	4 cases
31 to 40 years	24 cases
41 to 50 years	8 cases
51 to 60 years	8 cases
61 to 70 years	2 cases
Unknown	1 case

The diagnostic classification was as follows:

Atrophic Arthritis	43 cases or 86%
Hypertrophic Arthritis	7 cases or 14%

The youngest patient was nineteen, the eldest, sixty-nine years. The sex distribution was: 38 female, 12 male. The length of treatment varied from about one week to about eight weeks, on an average four weeks.

The results obtained were:

Moderate relief	44 cases or 88%
Marked relief	3 cases or 6%
No relief	3 cases or 6%

No symptoms or signs were observed traceable to renal, gastrointestinal or hepatic dysfunction.

The above two series are obviously antithetic as regards etiology, sex, and, to a certain extent, the distribution. Nevertheless, together they cover nearly the whole range of ambulatory arthritis. In general, the symptom to be re-

Tolysin medication—30 gr./day

lieved by medication, pending the institution of curative processes by nature and the physician, was pain. It is remarkable that, with the very small doses employed, only 3 per cent, and about the same in each series, were not relieved. The medication was obviously minimal in both series and apparently satisfactory. No toxicity was expected or observed.

It seemed to one of us (D. S.) that further, more detailed studies with extensive laboratory functional tests were indicated at higher dosage levels. Accordingly, a series of 23 cases, drawn from the wards of Temple University Hospital and Lankenau Hospital was studied quite carefully. It should be

SCHEMATIC OUTLINE

Curves approximate only in terms of dye retention.

Chart II.

noted that this series was studied not for relief of pain, or for associated phenomena in arthritis, but principally to learn something of the organic functional response of arthritic patients to antirheumatic medication. To give the complete history and physical examination on each of these cases, in addition to the laboratory results, would consume entirely too much space; in fact, it is impossible to more than approximate the laboratory findings after medication was instituted. Almost 600 special laboratory, x-ray, blood pressure, and consultation examinations were made on the 23 cases. It must be pointed out that, in the tables subjoined, the tests representing work done during or after medication are always taken as the worst or least favorable test; and usually

represent three or more tests during that period upon that particular function. We have tabulated the laboratory findings in brief as follows:

Group I	13 cases under tolysin medication
Group II	5 cases under minimal salicylate and iodide medication
Group III	5 cases under standard salicylate and sodium bicarbonate medication
Group IV	Significant blood findings
Group V	Comparative B.S.P. findings
Group VI	Comparative P.S.P. findings

GROUP SIX -COMPARATIVE PHENOLSULPHONEPHTHALEIN FINDINGS

DISCUSSION OF TABULATED CASES

It will be noted in all the tables that it was impossible, due to the exigencies of hospital routine, to do every test upon every patient. Many more tests were done after, or during, medication than before. A consideration of all the findings gives at least temporary answer, however, to the question of the extent to which renal and hepatic functions are affected by standard moderate medication under the conditions of the study. On an average, three functional studies of the P.S.P., B.S.P., and icterus index were done for each one reported in the tables; but the graphic charts are inclusive of nearly all. An interesting point was that nearly all cases of arthritis due to infection show traces of albumin in the urine either before or after treatment, or both.

Case 9248.—T. U. (Table I), is interesting in that the case was clearly one of slightly impaired renal and hepatic function evidenced by the slightly raised icterus index and slightly subnormal P.S.P., and one positive indirect van den Bergh. Yet, under three weeks' medication with tolysin, the patient showed no significant change in the functional indices. Case 10726, T. U., showed a slightly raised icterus index, but no other signs. Case 7158, T. U., had all the evidence of focal infection over many years; but the E.K.G. did not reveal any wave abnormality; and the laboratory findings were normal. Case 8533, T. U., was of typical rheumatic origin. The heart was enlarged and there was an insufficiency of the mitral valve. E.K.G. showed extrasystoles and left axis deviation. The P.S.P. in this case was consistently low; but all other tests were approximately normal. On Case 8891, T. U., we did a *Mosenthal* test and found an ability to concentrate that was definitely diminished; yet the blood chemistry, P.S.P., and urinalysis showed insignificant changes. Liver function tests in the case were entirely normal. Case 1450, L. K., showed consistently low and declining P.S.P. without any other significant findings except a Wassermann and Kahn reaction first reported positive, then negative. In Case 1027, L. K., it was interesting to correlate the declining blood urea nitrogen with a rising P.S.P. output, the liver function test being essentially normal. Case 7664, T. U., showed definite progressive diminution in function of the kidney by P.S.P. test; but the icterus index improved while the galactose test was, and remained, poor, suggesting a renal factor. Case 7423, T. U., showed normal function test, a normal E.K.G., but a typical rheumatic history and was, in fact, a typical case of rheumatic disease. All of the above cases were treated, so far as analgesic medication was concerned, with 10 gr. of tolysin three times a day. So far as could be noted, there were no evidences of significant change in the laboratory tests after medication.

Group II cases were treated (Table II) upon a complex and somewhat irrational mixture known as elixir sodium salicylate, compound (N. F.) in amounts which would give a dose of about 18 gr. of the salicylate and $3\frac{1}{2}$ gr. of KI per day. At first it was thought to use a placebo in these cases; but the presence of a very small amount of the salicylate in the mixture gave it some effect and satisfied the patients. Case 863, L. K., was an interesting one because of the absolutely negative findings in the liver function test in the presence of clear abnormality elsewhere. Here the P.S.P. declined progressively; focal infection was obviously present in the tonsils; the blood urea nitrogen was definitely raised; yet the urine did not show much albumin and no sugar despite a very definite hyperglycemia. The case strikingly demonstrated the advisability of blood dextrose determinations in such cases. Case 1329, L. K., is interesting because, on physical examination, the liver was found considerably enlarged. The functional tests were, without exception, normal. Case 1122, L. K., is worth consideration since it was the only one in the series of 23 hospital cases in which a definitely abnormal B.S.P. was found after mild medication. Seven days later, however, the B.S.P. was normal as

were all other tests at all times; and as a consequence the significance of the findings, if any, cannot be determined. Case 1179, L. K., had several interesting features, including an abnormal B.S.P. became normal after a few days' stay in the hospital; a consistently low P.S.P. unassociated with albumin or casts in the urine; and a normal icterus index with improving B. S. P. It was interesting to note that during this period his liver, by physical signs, progressively enlarged. We offer no explanation. This single group was, in a loose sense, a control group. Nothing abnormal was expected or noted.

Group III (5 cases) represented standard dosage with sodium salicylate and sodium bicarbonate, antiarthritic medication widely recognized in hospitals. All of these cases showed one or more interesting points. All had a definite rheumatic fever history and in all the diagnosis of acute rheumatic fever was justified. None showed any significant change in laboratory findings under the above medication, and particularly was the liver function free from such change. In three cases there was a definite trend downward (rather than upward as claimed by the protagonists of sodium bicarbonate) in the P.S.P. test (Cases 8529, T. U.; 9343, T. U.; 9836, T. U.), but this change was commonly later reversed. The E.K.G. findings showed cardiac involvement in two cases (Cases 8000, T. U., 5693, T. U.).

The subject of blood studies has not been mentioned up to this point, but in these 23 cases some blood work was done on each, and a great deal of work was done on many. In some, the so-called "Schilling hemogram" was constructed to indicate comparatively the complete count (repeated from five to ten times) together with an estimate of the shift in the nuclear structure of the white cells "to the left" or "to the right." In this regard we have been very much interested in the recent publication by Steinbrocker and Hartung¹⁸ on the "filament-nonfilament count" of arthritis as an aid in differential diagnosis. We have scarcely space to go into an analysis of these cases as viewed from such an angle, but hope to be able to do so in a subsequent publication. Solely to illustrate the constant tendency to hypochromic anemia in these cases, we have appended a few rough diagrammatic charts of the course of the red cells, hemoglobin and white count. It is our preliminary opinion that the hypochromic anemia, which almost invariably occurs in these cases, is best treated when infection is quiescent and hemolysis has ceased.²³ We should like to call attention to the article by Robertson, Swalm, and Konzelmann¹⁹ in which an excellent summary of liver function tests is given. We have made no attempt to use the recently suggested Lichtman²⁰ test of hepatic function because of the difficulty of obtaining betahydroxyphenyleinchoninic acid for the preparation of standards.

SUMMARY

No essential difference was noted in the clinical response of 120 unselected cases of arthritis to minimal doses of tolysin or sodium salicylate in grain-for-grain equivalent dosage. The presence of potassium iodide, cimicifuga, gel-

seminum, and such medicaments did not seem to add to, or detract from, the effects noted.

The thirteen cases under 30 gr. of tolysin daily, carefully studied upon hospital wards, showed no signs of liver involvement which could be confirmed by any of the common laboratory functional tests frequently repeated, and the kidney signs were in conformity with the usual findings of a slight albuminuria in arthritis regardless of medication. In this matter, our experience coincides with that of Chace, Myers and Killian²¹ who remarked over ten years ago, after careful study: "In the cases which we employed, neither cinchophen nor neocinchophen produced proteinuria or intensified it when already present. . . ."

The series of five cases upon very small doses of salicylates (Group II) failed to differ materially from any of the others from a laboratory standpoint.

The series of five cases upon standard salicylate medication averaging more than 80 gr. of sodium salicylate per day (Group III) together with sodium bicarbonate, differed not at all from the preceding cases in the character of their functional tests.

The entire study failed to show any effects of so-called toxicity from anti-rheumatic medication in moderate or small dosage during the period of study and with the dosages employed. We wish at this point to express our great appreciation to Doctors Robertson, Konzelmann, Kline and Bortz for their co-operation; and to Miss Schubert and Miss Hohl for assistance in the pathologic work.

CONCLUSIONS

1. Moderate dosage of tolysin and sodium salicylate with bicarbonate, produced no appreciable changes in the laboratory tests for total renal and hepatic function in arthritic cases under the conditions of our study.

2. Hypochromic anemia is an almost constant concomitant of acute and chronic nontraumatic arthritis.

3. The widely accepted treatment of arthritis, involving accurate diagnosis; anti-etiological measures; anatomic, physiologic and psychic rest; the regulation of bodily and endocrine chemistry, is best charted and checked by careful functional laboratory studies.

A STUDY OF THE OTTO TEST FOR STRYCHNINE*

CHARLES F. POE, PH.D., AND JOHN F. BAILEY, M.A., BOULDER, COLO.

ONE of the earliest tests devised for the detection of the presence of strychnine was proposed by Otto¹ in 1846. This test consists of treating a small quantity of strychnine with a few drops of concentrated sulphuric acid. When a small crystal of potassium dichromate is moved about in this liquid a deep violet color changing to a dirty green is produced.

A study in this laboratory² has shown that the Mandelin test for strychnine is given by a number of substances other than strychnine. A study was therefore undertaken in order to determine whether or not the Otto test was more specific for strychnine than was the Mandelin test.

A record has been made of a number of substances which produce a color similar to that given by strychnine with $\text{H}_2\text{SO}_4 - \text{K}_2\text{Cr}_2\text{O}_7$. Wormley³ states that curarine and cod liver oil give a similar test. Witthaus⁴ lists geissospermin as giving the same test as strychnine, while aniline at first gives the test but soon changes to a black. A number of substances are listed by Wormley³ which will interfere with the test. These include morphine, quinine, sugar, brucine, and tartar emetic.

In working with crude drugs, Fuller⁵ has found that the petroleum ether residues from gelsemium and yohimbe give the strychnine test.

Mameli⁶ made a study of the interference of certain substances employed in therapeutics on the Otto color reaction. He found a number of drugs which more or less interfered with the test. The amounts of the drugs used in the tests, however, were not given.

PROCEDURE

Preparation of Solutions to Be Tested.—The organic compounds used in this investigation were prepared in the proper solvent so that 1 c.c. was equivalent to 1 mg. of the compound. The strychnine solution was of the same strength.

Procedure of the Tests.—Three tests were made on each compound. For the first, 1 c.c. of the solution of the organic compound was evaporated and the usual test was made and any color noted. The second test was made in the same manner except that 1 c.c. of strychnine was evaporated with the same volume of the organic compound and the test made on the mixture. The third test was carried out as above, except that 5 c.c. of the impurity were mixed with the strychnine.

The results of the tests when the organic compounds were tested alone are given in the pages which immediately follow: The name is given first and directly opposite is given the color reaction.

ALKALOIDS AND ALKALOIDAL SALTS

<i>Organic Substances</i>	<i>Color Reaction</i>
Apomorphine	Brownish green
Berberine	Brown to black
Brucine	Orange
Colchicine	Orange, acid alone
Cotarnine hydrochloride	Orange
Cryptopine	Violet, acid alone
Delphinine	Reddish brown, acid alone
Gelseminine	Reddish brown
Hydrastine	Yellow, trace of violet
Papaverine	Light violet, acid alone
Piperine	Violet brown
Sanguinarine nitrate	Greenish black, acid alone
Solamine	Yellow, acid alone
Strychnine	Violet to blue to orange
Veratrine	Orange to red, acid alone

No Color Reaction.—Aconitine, atropine, belladonnine, caffeine, cinchonidine, cinchonine, cocaine, codeine, daturine, dionine, emetine, ergotine, beta-eucaine hydrochloride, heroine, homatropine, hyoseyamine, morphine, narceine, nicotine, pelletierine, phenacaine, physostigmine, pilocarpine, pseudopelletierine, quinidine, quinine, scopolamine, sparteine, theobromine, theophylline.

AMINO ACIDS AND DERIVATIVES

Glycyltryptophane	Dirty green
Phenylglycine	Violet brown
Tryptophane	Dirty green, trace purple

No Color Reaction.—Acetylphenylglycine, alpha-alanine, para-aminophenylglycine, arginine, asparagine, aspartic acid, *dl*-benzoylalanine, betaine hydrochloride, creatine, creatinine, diiodotyrosine, edestine, ethylglycollate, glutamic acid, glycine, hippuric acid, isoleucine, leucine, para-nitrophenylglycine, alpha-phenylalanine, beta-phenylalanine, tyrosine, *dl*-valine.

ALIPHATIC ACIDS

No Color Reaction.—Aconitic acid, adipic acid, *dl*-alpha-aminoacetylacetic acid, alpha-bromopropionic acid, beta-bromopropionic acid, formic acid, fumaric acid, levulinic acid, maleic acid, malic acid, malonic acid, mesaconic acid, mucic acid, palmitic acid, propionic acid, stearic acid, succinic acid, tartaric acid, tartronic acid, trichloroacetic acid.

ALIPHATIC ACID SALTS, ESTERS, AND DERIVATIVES

No Color Reaction.—Ethyl oxalate, ethyl succinate, isoamyl propionate, isobutyl acetate, isobutyl isothiocyanate, methyl isothiocyanate, sodium formate, sodium oxalate, thallous formate, thallous malonate, triacetin, tributyrin.

ALIPHATIC ALCOHOLS AND KETONES

No Color Reaction.—Acetylacetone, cetyl alcohol, dulcitol, erythritol, ethylene glycol, isobutyl alcohol, isopropyl alcohol, mannitol, melissyl alcohol, methyl heptenone, octyl alcohol, phorone, trichlorobutyl alcohol.

SUGARS

No Color Reaction.—Arabinose, galactose, glucose, lactose, levulose, maltose, *d*-mannose, melezitose, raffinose, rhamnose, sucrose, xylose.

UREA AND URIC ACID DERIVATIVES

Allylphenylthiocarbamide	Brown, streaks of violet
Amytal (isoamylethylbarbituric acid)	Light green
Triphenylguanidine	Brown to green

No Color Reaction.—Allylthiocarbamide, allylthiourea, acetyl methylurea, allantoin, alloxantine, barbital (diethylmalonylurea), barbituric acid, biuret, *dl-n*-butylthiourea, dibromobarbituric acid, diphenylthiourea, guanine hydrochloride, ipral (calcium ethylisopropylbarbiturate), luminol (phenylethylbarbituric acid), peralga (aminopyrinediethylbarbiturate), thiobarbituric acid, thiourea, urea, urethane, uric acid.

GLUCOSIDES

Aesculin	Brown, trace violet
Arbutin	Reddish violet, acid alone
Colocynthin	Yellow, acid alone
Digitalin	Reddish brown, acid alone
Salicin	Magenta, acid alone
Saponin	Brown, acid alone

No Color Reaction.—Amygdalin, convallamarin, elaterin, phloridzin, picrotoxin, santonin.

MISCELLANEOUS ALIPHATIC COMPOUNDS

Oenanthal	Green
-----------	-------

No Color Reaction.—Acetal, acetaldoxime, acetamide, acetoxime, aldehyde ammonia, aminoguanidine bicarbonate, bromoform, *ter*-butyl bromide, chitin, chloral hydrate, chloral urethane, chloropierine, dimethylglyoxime, hexachloroethane, hexamethylenetetramine, iodoform, isobutylbromide, methylglyoxal sodium bisulphite, monochlorohydrine, nitrosodiethylamine, oxamide, pinacol hydrate, propionamide, sulphonal, thialdine, tribromohydrine, trichloroacetylchloride, trimethylene bromide, trional, veronal.

BENZENE AND TOLUENE DERIVATIVES

Azoxybenzene	Brown
--------------	-------

No Color Reaction.—Ortho-bromochlorobenzene, para-bromochlorobenzene, ortho-bromonitrobenzene, meta-chloronitrobenzene, ortho-chloronitrobenzene, para-chloronitrobenzene, para-chlorotoluene, ortho-dichlorobenzene, 2-5-dichloronitrobenzene, iodosobenzene, isopropylbenzene, meta-nitrotoluene, ortho-nitrotoluene, para-nitrotoluene, mesitylene, styrene, para-xylenesulphonic acid.

ANILINE AND DERIVATIVES

ortho-Anisidine	Violet black, acid alone
Benzanilide	Deep violet
ortho-Benztoluide	Reddish violet
para-Bromoaniline	Reddish violet to brown
ortho-Phenetidine	Deep violet, acid alone
para-Phenetidine	Light violet, acid alone
Phenyl-beta-diphenylamine	Green, acid alone
ortho-Tolidine	Deep orange

No Color Reaction.—Acetoanilide, acetyl-para-anisidine, acetyl-ortho-methyltoluidine, acetyl-para-methyl-toluidine, acetylphenetidine, acetyl-ortho-toluidine, acetyl-para-toluidine, meta-acetylidine, aminoazobenzene, 2-aminotoluene-4-sulphonic acid, 2-aminotoluene-5-sulphonic acid, 4-aminotoluene-2-sulphonic acid, aniline, meta-anisidine, para-anisidine, para-benztoluide, para-bromoacetanilide, meta-bromoaniline, ortho-bromo-aniline, chloramine, meta-chloroaniline, ortho-chloroaniline, para-chloroaniline, 1, 2, 4-dichloroaniline, 2, 5-dichloroaniline, 1, 2, 4-dinitroaniline, exalgine, meta-nitroaniline, para-nitroaniline, meta-nitrodimethylaniline, para-nitrodimethylaniline, nitroso-dimethylaniline, 1, 2, 3-nitrotoluidine, 1, 2, 4-nitrotoluidine, 1, 3, 4-nitrotoluidine, meta-toluidine, ortho-toluidine, para-toluidine, tribromoaniline, trinitroaniline, 1, 2, 4-xylydine, 1, 3, 4-xylydine.

PHENOLS AND DERIVATIVES

meta-Aminophenol	Dirty green
ortho-Aminophenol	Light violet, acid alone
para-Aminophenol	Blue black, acid alone
5-Benzalmino-2-cresol	Yellowish green, acid alone
para-Benzalaminophenol	Green, acid alone
Catechol	Green, acid alone
ortho-Chloromercuriphenol	Yellowish green
para-Nitrophenol	Pink
Phloroglucinol	Slate to green

No Color Reaction.—Acetyl-meta-aminophenol, acetyl-para-aminophenol, benzoylthymol, para-bromophenol, carvacrol, ortho-chlorophenol, para-chlorophenol, meta-cresol, ortho-cresol, para-cresol, 3, 5-dibromo-ortho-cresol, 2, 4-dichlorophenol, dimethylhydroresorcinol, 2, 3-dinitrophenol, 2, 4-dinitrophenol, 2, 6-dinitrophenol, meta-nitrophenol, ortho-nitrophenol, orcinol, phenol, picric acid, pyrogallie acid, tetrabromo-ortho-phenol, thymol, tribromophenol, trichlorophenol, xylenol.

AROMATIC ACIDS

Anisic acid	Brown, tinge of violet
Benzilic acid	Magenta, acid alone
Cinchophen	Light green
Cumaric acid	Red to green
Diiodosalicylic acid	Dark yellow
Diphenylacetic acid	Yellow to dark green
Mandelic acid	Brown

No Color Reaction.—Acetylsalicylic acid, meta-aminobenzoic acid, para-aminobenzoic acid, *dl*-aminophenylacetic acid, anthranilic acid, arsanilic acid, meta-bromobenzoic acid, ortho-bromobenzoic acid, para-bromobenzoic acid, meta-chlorobenzoic acid, ortho-chlorobenzoic acid, para-chlorobenzoic acid, cinnamic acid, gallic acid, 5-iodosalicylic acid, para-mercuri-chlorobenzoic acid, metanilic acid, naphthionic acid, meta-nitrobenzoic acid, ortho-nitrobenzoic acid, para-nitrobenzoic acid, quinic acid, salicylic acid, tannic acid, terephthalic acid, ortho-toluic acid, para-toluic acid.

AROMATIC ACID DERIVATIVES

Benzyl benzoate	Brown
Neocinchophen (ethyl-6-methyl-2-phenylquinoline-4-carboxylate)	Brownish green

No Color Reaction.—Benzamide, benzoic anhydride, butyl benzoate, cumarin, ethyl benzoate, ethyl salicylate, isoamyl benzoate, isoamyl salicylate, isobutyl benzoate, methyl benzoate, methyl cinnamic ester, methyl salicylate, nicotinic acid nitrate, meta-nitrobenzoyl chloride, para-nitrobenzoyl chloride, phenyl salicylate, phthalimide.

AROMATIC ALDEHYDES, ETHERS, ALCOHOLS, AND KETONES

Benzalacetophenone	Brown
ortho-Nitrobenzaldehyde	Red, acid alone
5-Nitrosalicylaldehyde	Dirty green
Salicylaldehyde methyl ether	Greenish brown, acid alone
Saligenin	Pink, acid alone
Vanillin	Brown

No Color Reaction.—Para-aminoacetophenone, anisaldehyde, anisole, benzalacetone, benzhydrol, benzophenone, ortho-bromoanisole, para-bromoanisole, ortho-bromonitrobenzaldehyde, 1, 2, 5-bromosalicylaldehyde, ortho-chlorobenzaldehyde, isophthalaldehyde, meta-methoxysalicylaldehyde, methylacetophenone, para-nitroanisole, phenetole, phthalic acid aldehyde, piperonal, salicylaldehyde, tetramethyldiaminobenzophenone, para-tolylaldehyde.

HETEROCYCLIC COMPOUNDS

Isatin	Brown
Piperidine	Brown

No Color Reaction.—Acridine, antipyrine, dimethyl-pyrone, furoic acid, 6-nitroquinoline, oxyquinoline, quinaldine, quinoline, skatole, succinimide.

HYDROAROMATIC COMPOUNDS

Carvene	Yellow-brown, acid alone
---------	--------------------------

No Color Reaction.—*d*-Borneol, *l*-borneol, *dl*-camphor (natural), camphor (synthetic), camphoric^o acid, camphor sulphonic acid, carvenone, limonene, menthol, quercite, terpineol, terpenyl acetate.

NAPHTHALENE AND ANTHRACENE DERIVATIVES

Alizarin	Reddish violet, acid alone
Dibromoanthracene	Light brown
beta-Naphthol	Green with black streaks
Naphtholmethyl-alpha-ether	Green, acid alone
alpha-Naphthylamine	Bluish grey, acid alone
alpha-Naphthylaminoazobenzene	Deep violet, acid alone
Nitroso-beta-naphthol	Brown, acid alone

No Color Reaction.—Acenaphthene, acet-alpha-naphthalide, acet-beta-naphthalide, alpha-bromonaphthalene, 1, 5-dinitronaphthalene, beta-naphthalenesulphonic acid, naphthalic anhydride, beta-naphthylamine, alpha-naphthylisocyanate.

MISCELLANEOUS AROMATIC COMPOUNDS

Amarine	Green
Benzocatechin	Dark green
Benzoïn	Green, acid alone
Benzylphenylhydrazine	Rose violet
Fluorene	Dark green
Phenanthrene	Greenish brown
Phenanthrenequinone dioxime	Reddish brown, acid alone
Phenolphthaleïn	Reddish orange, acid alone
meta-Phenylenediamine hydrochloride	Black, acid alone
Tetrabromophenolphthaleïn	Violet red, acid alone
Thymolphthaleïn	Magenta, acid alone
Triphenylmethane	Brown, traces of violet

No Color Reaction.—Abeitic acid, adrenaline, benzil, 2, 4-dinitrophenylhydrazine, diphenyl, isoamylphenylhydrazine, isoeugenol, ortho-nitroacet-meta-xylidide, meta-nitrobenzhydrazide, para-nitrophenylhydrazine, phenylhydrazine hydrochloride, quercite, rheumatine (saloquinine salicylate), salvarsan, thiosemicarbazide, ortho-tolunitrile, para-tolunitrile, para-tolylisothiocyanate, para-tolylquinolinesulphate, para-tolylthioquinanthrene, tumeric.

The color reactions for the tests where an equal amount of impurity was added to the strychnine were recorded, and also the reactions where five times the amount of impurity was added; but the listing of these would require too much space. Therefore, only those compounds which caused the violet color to be completely masked will be given. With the remainder of the compounds, many gave no interference, whereas others gave more or less interference.

Organic compounds which completely covered up the Otto test for strychnine when present in equal amounts were: Aesculine, meta-aminophenol, azoxybenzene, benzoic acid, benzohydrol, para-benzotoluide, dionine, diphenylacetic acid, diphenylthiourea, beta-naphthol, alpha-naphthylamine, alpha-naphthylisocyanate, phenanthrenequinone dioxime, rheumatine, thymolphthaleïn, orthotolidine.

Organic compounds which completely covered up the Otto test when present in amounts five times that of strychnine, in addition to those listed above were: Acet-alpha-naphthalide, acet-beta-naphthalide, meta-acetxylidine, acetyl-meta-aminophenol, acetyl-para-aminophenol, acetyl-para-anisidine, amarine, aminoazobenzene, para-aminophenol, apomorphine, benzalacetophenone, 5-benzal-amino-2-cresol, para-benzalaminophenol, benzophenone, berberine, brucine, orthochloromercuriphenol, colocynthin, cotarnine hydrochloride, diiodosalicylic acid, elaterin, heroine, 5-iodosalicylic acid, isoamylsalicylate, isoeugenol, morphine, beta-naphthalenesulphonic acid, naphthionic acid, naphtholmethylalpha-ether, beta-naphthylamine, neocinchophen, meta-nitrophenol, para-nitrophenol, nitroso-beta-naphthol, oenanthol, phenacaine, phenanthrene, phloridzin, phloroglucinol, piperine, salicin, sanguinarine nitrate, thiosemicarbazide, paratolylisothiocyanate, triphenylguanidine, tryrosine, veratrine.

When a study is made of the preceding data, it will be noted that there were twenty-three compounds which gave some shade of violet, lavender, or purple. Some of these were very similar to the strychnine test and might be mistaken for

it. Of these twenty-three tests, there were eleven which gave the violet, lavender, or purple color with the sulphuric acid alone. The color with the acid would account for some of the positive tests which are obtained with such reagents as Fröhde's, Mandelin's, and the dimethylaminobenzaldehyde reagent.

In general, the compounds giving a test similar to that of strychnine belong to no definite group. The alkaloids and aniline derivatives, however, gave the largest number of positive tests.

There were a few organic compounds which interfered with the test. Many of these, however, would be removed by different organic solvents in a carefully conducted analysis.

There were somewhat fewer positive tests for strychnine given by the Otto test than by the Mandelin test, but the number of substances which interfered with the former test was somewhat greater.

CONCLUSIONS

1. A large number of organic compounds have been tested with the Otto-Strychnine reaction. A number of compounds have been found which give the same test as does strychnine.

2. The interferences caused by organic compounds as impurities have been determined.

STUDIES OF THE MECHANISM OF PAIN IN PEPTIC ULCER*

EMIL GRANET, M.D., NEW YORK, N. Y.

SEVERAL theories have been advanced by various authors in an attempt to explain the mechanism of pain in peptic ulcer. These theories may be discussed under the following headings:

1. Increased muscle tension
2. Chemical irritation of the ulcer
3. The compression theory of Kinsella

1. *Muscle Tension Theories.*—Hurst in 1911¹ considered that pain in peptic ulcer was due to strong peristaltic waves advancing against a pylorus that fails to relax, "achalasia." Glaessner, Kreuzfuchs, and others thought that spasm of the pylorus and of the duodenal cap was the most important factor in ulcer pain.

Carlson, Guinzburg and associates, Hardt, and others made kymographic tracings from intragastric balloons. These tracings showed that pain was felt at the time of or just after maximum hunger contractions.

Reynolds and Mc Clure² observing ulcer patients fluoroscopically found various types of motor phenomena during the painful phase in patients with peptic ulcer. The motor activity varied from quiescence to intense activity.

Ortmeyer,³ on the other hand, observed that no change occurred in the character of gastric contractions during relief of pain by alkalies.

Wilson⁴ examined fluoroscopically 16 duodenal ulcer patients while in pain. He found contracted, spastic duodenal caps in all of these patients. By manual manipulation he managed to partially fill the duodenal cap in 13 of the 16 patients. Relaxation shown by filling of the cap was immediately followed by pain relief in all of the 13 cases. Wilson concluded with the hypothesis "that relief of pain is due to relaxation of musculature of the caput and conversely, that pain is due to overaction of the duodenal caput with or without abnormal local contraction or implication of the pyloric sphincter."

Apparently increased tissue tension, due to contraction of muscle or increased peristalsis, plays a rôle in the mechanism of pain in patients with peptic ulcer.

2. *The Theory of Chemical Irritation of the Ulcer.*—That pain in duodenal ulcer cases can be caused by exposing the ulcer to the action of hydrochloric acid has been shown by Bonninger.⁵

Palmer⁶ showed that when a sufficient quantity of 0.5 per cent hydrochloric acid was injected into the stomach of a patient with peptic ulcer, in the active stage of the disease, typical ulcer pain was produced in 95 per cent of his cases.

*From the Gastro-Enterological Clinic of the Mount Sinai Hospital.
Received for publication, October 29, 1932.

After the onset of pain, aspiration of the entire contents of the stomach resulted in immediate relief. Ingestion of alkalis sufficient to considerably reduce the acidity of stomach contents also resulted in pain relief. He further showed that as the ulcer patient became symptom-free, the pain-sensitizing action of 0.5 per cent HCl. becomes less. Palmer regards this reaction as an index of healing in ulcer.

Hurst, and Reynolds and Mc Clure failed to cause ulcer pain by injection of hydrochloric acid.

Despite this, it seems apparent that in peptic ulcer under certain conditions, the acidity of the gastric contents is a factor in the mechanism of ulcer pain.

3. *Compression of Sensory Nerves.*—Kinsella⁷ in a very complete monograph criticizes previous attempts to explain the pain mechanism in ulcer as being too limited in their scope. He introduced a concept whereby ulcer pain is explained primarily by compression of sensitized sensory nerves in and around the ulcer base.

Kinsella points out that a moderate amount of compression is exerted by the edema and inflammatory exudate on the intrinsic sensory nerves around the ulcer base. Peristalsis and muscle spasm following a meal, augment this tension. Furthermore, at a specific interval after eating, the vascular channels of the antral and pyloric regions become engorged, thereby adding still another factor to increase local tension. Compression, therefore, is attained by the summation of the three factors; inflammatory edema, increased muscle tone or spasm, and localized vascular engorgement, all occurring in and around the ulcer at a specified time after meals. Kinsella concludes that ulcer pain is caused by compression of sensitized nerves around the ulcer at that time. Ulcer pain relief depends on decrease in tissue tension. Alkalis, when ingested, relax the musculature of the pylorus and duodenum. This was shown roentgenographically by Carman and by Kinsella. Food ingestion also decreases ulcer pain. As the stomach fills, the entire gastric vascular bed becomes engorged. In order to supply part of the required blood to the entire stomach, the vascular engorgement of the ulcer area necessarily diminishes. As local engorgement decreases, so also does the tissue tension in the ulcer region, and hence the compression pain is relieved.

I. INDIVIDUAL SENSITIVITY TO PAIN

Another factor is probably of prime importance in the problem. This consists in the individual susceptibility of the patient to pain.

Libman⁸ pointed out in 1926 that individuals may vary widely in their sensitivity to a standard pain-producing stimulus. He stressed the problem in relation to coronary artery disease and also ulcer.

Later Crohn⁹ reported that in hyposensitive individuals, peptic ulcer caused little or no pain. Hypersensitive individuals, on the contrary, definitely experience the pain caused by their ulcer. Individual sensitivity to pain seems so important a factor in interpreting symptomatology that it was decided to reinvestigate the relationship of factors associated with ulcer pain in the light of individual pain sensitivity.

The subjective symptom of pain in disease seems dependent upon the sensitiveness of the individual. Thus the phlegmatic Nordic may respond less actively to a standard painful stimulus than the hypersensitive Latin. A simple clinical test was introduced by Libman so that patients can easily be examined as to their individual pain sensitiveness. The test is performed as follows: The examiner, using the side of the ball of his thumb, makes firm pressure first on the mastoid, then on the styloid process between the tip of the mastoid and the angle of the jaw of the patient. Both sides are examined. The mastoid is the control point. The response of the patient to styloid pressure constitutes an index of pain sensitivity. A normal response is interpreted by a facial contortion indicating pain; hypersensitive patients wince, jerk the head away, and often cry out with pain; hyposensitive patients have slight or no change in their facial expression despite a strong increase in thumb pressure. In these studies patients were classified as normal; hypersensitive, 1-plus and 2-plus; hyposensitive, 1 minus and 2 minus. A significant fact in working with Libman's valuable clinical sign is that psychic manifestations or so-called "nervousness" and pain sensitivity are not directly related. That is, an individual may be insensitive to pain as determined by styloid pressure and yet be markedly psychoneurotic.

The relationship of typical peptic ulcer symptomatology to pain sensitivity of the individual as determined by Libman's sign was investigated. All patients were classified in two groups according to subjective symptoms. Patients were considered typical in symptomatology when they complained of localized epigastric pain definitely related to meals, pyrosis, night pain, possibly vomiting; these symptoms often being relieved by the ingestion of alkalis and food. The symptomatology was considered atypical if pain was vague or absent or if substitution symptoms, such as gas or heart burn or pressure alone were present. Cases were also considered atypical where the diagnosis of ulcer was made after investigation of the patient for painless hematemesis, painless vomiting, and for the vague painless dyspeptic symptoms just described. Three cases of sudden perforation with no previous gastric symptoms were included.

Material.—Ninety-nine patients with duodenal ulcer were studied and 120 clinical observations made. Sex distribution: Male 80, and female 19. Youngest twenty-one, and oldest sixty-seven years. Duration of ulcer symptoms: Shortest three weeks, and longest twenty years.

The presence of ulcer was proved roentgenographically in all cases and confirmed by operation in 12.

Observations.—In this group of 99 patients taken as a whole, sensitiveness as tested by Libman's sign was distributed as follows: Normal 28, hypersensitive 31, and hyposensitive 40. The preponderance of individuals hyposensitive to pain is possibly to be expected in this dispensary group, more exposed and accustomed as they are to rigorous conditions of life.

In eliciting the history we found that 74 (75 per cent) of our 99 patients had symptoms at some time which were typical of peptic ulcer. This group of ulcer cases with typical symptoms when examined for pain sensitivity by Lib-

TABLE I

PEPTIC ULCER SYMPTOMATOLOGY AND PAIN SENSITIVENESS. PATIENTS EXAMINED, 99

SYMPTOMS	CASES	PAIN SENSITIVENESS
Typical	74 (75%)	26 (35%) Hypersensitive
		23 (31%) Normal
		25 (34%) Hyposensitive
Atypical	25 (24%)	5 (20%) Hypersensitive
		5 (20%) Normal
		15 (60%) Hyposensitive

man's test were equally distributed in the three groups: Normal (23 per cent), hyposensitive (25 per cent), and hypersensitive (26 per cent) (Table I). Twenty-five ulcer cases with atypical symptoms had little or no pain. In these atypical cases we rather expected to find hyposensitiveness to pain according to Libman's test. Actually 15 cases (60 per cent) were hyposensitive, 5 cases (20 per cent) were hypersensitive, and 5 cases (20 per cent) were normal when tested.

II. PAIN DUE TO THE COMPRESSION FACTOR AS TESTED BY PERCUSSION TENDERNESS

During the examination of patients in the active stage of peptic ulcer, it was noted that percussion in the epigastric region revealed a localized point of tenderness. This area, in size no larger than a half dollar, was definite in its demarcation from the remaining relatively insensitive epigastrium. A tender point in the epigastrium similar to the above has been mentioned by Mac Lean, Crohn, and Bolton in writing on the physical diagnosis of ulcer. Bolton called it the "Hyperalgesic Point." To elicit percussion tenderness, fairly heavy percussion is made on the relaxed epigastrium of the supine patient. If a point of definite and sharply localized tenderness is not found, percussion is repeated after the patient has been asked to inspire and hold the breath in deep inspiration. In calling this sign "positive" it is essential to observe that the tenderness must be definite and sharply localized in area. Patients having slight, absent, or mild diffuse tenderness, are considered "negative."

The mechanism involved is not entirely clear. It is probable that in percussing, the plexor impulse is transmitted by vibration through the abdominal wall and intermediate tissues directly to the inflamed region surrounding the ulcer base. This vibratory impulse affects the inflamed nerves already under tension in the indurated tissues around the ulcer. It is also possible that the intragastric pressure and the tissue tension may be increased directly or reflexly by this maneuver. This sudden mechanical disturbance results in the production of momentary pain directly under the pleximeter finger. The use of percussion in the erect position as a diagnostic measure in ulcer has been described by Erhlich in 1923 and Kohn in 1928.

Ninety-nine patients were examined for tenderness to percussion using the technic just described. A positive reaction was found in most patients examined during the stage of ulcer activity. Patients examined in the remission or inactive, symptom-free stage of the disease were usually negative to "percussion tenderness."

The statistics are as follows:

Fifty-five (46 per cent) observations were made while the patients were in the active symptomatic stage of the disease. Forty-seven (85 per cent) of these responded positively when examined by percussion tenderness. Only 8 (15 per cent) active cases were negative to percussion. Six of these were hyposensitive when examined by Libman's test. In these individuals, possessing apparently a high threshold of pain sensitiveness, it is likely that percussion is an inadequate stimulus for eliciting pain.

Arbitrarily we considered that one week or longer of freedom from ulcer symptoms placed the patient in the remission or inactive stage of the disease. Sixty-five (54 per cent) patients were examined while symptoms were not active. Some of these had previously been examined in the active stage. Of these 65 inactive cases, 46 (71 per cent) were negative for "percussion tenderness." Despite inactivity at the time of examination, 19 (29 per cent) showed positive "percussion tenderness." Many of these had been recently active (one to four weeks previously). It is possible that the pain producing factor, which can be induced by percussion, is still active despite the absence of ulcer symptoms.

Table II shows the relationship of "percussion tenderness" to symptomatology, the Palmer Test, and pain sensitivity. Patients showing positive percussion tenderness usually had typical symptoms (88 per cent). Seventy-

TABLE II

THE RELATIONSHIP OF "PERCUSSION TENDERNES" TO SYMPTOMATOLOGY, ACTIVITY, PAIN SENSITIVENESS AND PALMER'S ACID TEST

MATERIAL: 120 EXAMINATIONS ON 99 CASES OF PEPTIC ULCER

"PERCUSSION TENDERNES"	SYMPTOMATOLOGY	ACTIVITY	SENSITIVENESS	ACID TEST
	Typical 57 (88%)	Active 48 (74%)	Hypersens. 23 (36%)	Pos. 20 (45%)
Pos. 65 (55%)	Atypical 8 (12%)	Inact. 17 (26%)	Normal 21 (32%)	Neg. 24 (55%)
	Typical 33 (60%)	Active 7 (13%)	Hypersens. 12 (24%)	Pos. 5 (12%)
Neg. 55 (46%)	Atypical 22 (40%)	Inact. 48 (87%)	Normal 14 (26%)	Neg. 37 (88%)
			Hyposens. 29 (52%)	

four per cent were in the active stage of the disease at the time of examination. The acid test meal was positive in 45 per cent. Sensitivity to pain in this group was equally divided into the normal, hyper-, and hyposensitive groups.

On the other hand, of the patients with negative "percussion tenderness," 87 per cent were in the inactive remission stage of the disease at the time of examination, 88 per cent were negative to the acid test and hyposensitive patients predominated over normal and hypersensitive in the ratio of 2 to 1. From this study it appears that a positive response to percussion tenderness is a valuable aid in the physical diagnosis of peptic ulcer especially in a patient with typical ulcer symptoms who is in the active stage of the disease.

III. PAIN DUE TO CHEMICAL IRRITATION PRODUCED BY HYDROCHLORIC ACID

As stated above Palmer found that hydrochloric acid produced pain in cases of peptic ulcer. Palmer's technic was carried out in 80 patients. Briefly this consisted in evacuating the contents of the fasting stomach and then instilling 200 c.c. of 0.5 per cent hydrochloric acid through the Rhexuss tube. Similar amounts of acid are instilled at half-hourly intervals for a total of 600 c.c. Pain, similar to usual ulcer pain of the individual, when produced within one and one-half hours after beginning the test indicates a positive response.

Observations.—Thirty-four patients were examined while in the active stage of the disease. Of these 21 (62 per cent) had a positive reaction, that is, typical ulcer pain was induced by the acid. Palmer reported that over 90 per cent of active cases gave a positive response to this test. Forty-six cases in

TABLE III

Hypersensitive	4	Hypersensitive	2
Hyposensitive	11	Hyposensitive	5

the remission stage were examined by the Palmer acid test. Only 3 (7 per cent) gave a positive response (Table III). The pain sensitivity of patients with positive Palmer tests was noted. No definite relationship was found in this small series (Table IV).

SUMMARY AND CONCLUSIONS

1. The rôle of muscle tension, chemical irritation, and nerve compression in the mechanism of ulcer pain is discussed.

2. The importance in the problem of individual sensitiveness to pain is stressed.

3. Studies in patients with ulcer in the active and remission stages show that (a) percussion tenderness (muscle tension and nerve compression) is present in 85 per cent of patients during the active period of the disease. This is a helpful sign in the physical diagnosis of ulcer. (b) Patients with typical ulcer history may be hypersensitive, hyposensitive, or normally sensitive to pain. (c) Patients with atypical ulcer symptomatology, however, are mostly hyposensitive to pain. (d) The Palmer Acid Test Meal (chemical irritation)

is positive in the majority of ulcer patients during the active stage and negative in the remission stage.

I wish to express my thanks to Dr. Asher Winkelstein, Chief of the Gastro-Intestinal Clinic of the Mount Sinai Hospital, for his suggestions and advice, and to Mrs. Bentrice Weil for her technical assistance.

FOOD ALLERGY AS A COMMON PROBLEM*

WARREN T. VAUGHAN, M.D., RICHMOND, VA.

THERE are two general types of food allergies, the fortunate and the unfortunate. The former comprise those who were lucky enough to become sensitive to foods which are eaten only intermittently or occasionally. They have no difficulty in attributing their untoward symptoms to the correct cause. Instinctively they thereafter avoid the offending foods and are relieved of their allergic manifestations. As we shall see this forms a large group and these "fortunate allergies" are usually considered nonallergic.¹

The second or unfortunate group suffer the misfortune of becoming sensitive to staple foods, foods eaten frequently, usually daily. Chronic exposure, resulting in more gradual evolution of symptoms, a realization that in the past all of these foods have been eaten with impunity, and an understanding that they are not naturally poisonous, all combine to keep the sufferer ignorant of the cause of his symptoms. The man who experiences an explosive outbreak of urticaria with the advent of each strawberry season finds no difficulty in discovering its etiology. Thereafter he avoids strawberries. His friend, with subacute or chronic symptoms and sensitive to wheat is less likely to spontaneously discover the source of his trouble.

The allergic group representing from 7 to 10 per cent of the entire population is recruited chiefly from the unfortunates.² The fortunates are usually considered as in the nonallergic group because they have at some time in the

*Presented before the Oklahoma City Clinical Society, October 31, 1932.
Received for publication, November 1, 1932.

past solved their own problem and at the time of questioning they have no allergic symptoms. I use the terms fortunate and unfortunate, since so far as we know at present it is to a great extent just an element of chance to what one will become sensitive.

Other terms might be equally appropriate, as minor allergy and major allergy; or acute and subacute or chronic; or simple and complex. Each of these classifications is open to some criticism. It is sufficient that we understand that in the minor or fortunate group we are dealing with transient or passing episodes while in the major or unfortunate group we are faced with the problem of an established malady.

MINOR ALLERGY AND TRANSIENT ALLERGY

I have felt that we should be able to reach a clearer understanding of food allergy were we to direct more attention to an understanding of the simple or transient episodic manifestations of the phenomenon. With this in mind I have made a study of a number of so-called nonallergies, searching for evidences of allergic reactions in the past. Analysis of only the first 100 questionnaires has been completed and while the series is not sufficiently large to justify final conclusions, the observations are most interesting. Among the 100 so-called nonallergies, we found histories of former acute allergic manifestations in 61 per cent. In an additional 11 per cent the story was suggestive but not definite. The remainder were negative. If to the 61 per cent we add the 7 to 10 per cent of frank allergies, we may infer from this series that upward of 70 per cent or more are allergic at one time or another. Of the 61 per cent, 46 gave positive histories for food allergy and almost without exception they could name the foods causing symptoms.

A comparison of the foods recognized by the patient as causing minor allergy with those found by testing to be responsible for major allergy is of interest (Table I). With the major allergies, I have found by skin tests³ that the following foods are chief offenders, in order of frequency; wheat, milk, bean, egg, and Irish potato. The minor allergies, on the other hand, name the following foods in order of frequency as chief offenders; cucumber, watermelon, strawberry, tomato, onion, and cabbage. In this group wheat does not appear at all, egg and milk only once, potato and bean only twice each. Most of the remaining foods are such as are eaten occasionally.

I find evidence in my studies that the normal physiologic tendency is toward a gradual loss of specific sensitizations. There has in the past been a rather general impression that once one becomes sensitized this specific sensitization tends to persist throughout life. But students of allergy have in the last few years had the opportunity of watching sensitizations appear and disappear, to be replaced by new ones. Likewise, serial retesting will show that foods and other allergens, once positive, sometimes become negative, while others formerly negative become positive. It is but a simple step farther to postulate that the natural tendency of specific sensitization is to a gradual disappearance. The rapidity of this disappearance depends of course upon the degree or intensity of the sensitization and also upon whether the reaction

is kept active by repeated or continued contact with the sensitizing allergen. If avoidance of contact could be carried out sufficiently long with every allergen, the probability is that our sensitizations would eventually disappear. New ones of course may take their places. Allergists for example have almost universally concluded that food allergy is better handled through the method of avoidance than with attempts at desensitization either orally or parenterally. Prolonged contact intensifies the allergic reaction and delays recovery. I refer here more particularly to food allergy. Perennial pollen desensitization is an apparent exception which, however, I believe that we can reconcile to the hypothesis.

As examples of transient allergy the following may be cited:

Mr. V. in the summer of 1929 experienced attacks of colitis with cramping pains and diarrhea each time that he ate peaches. Almonds which belong to the same biologic group as the peach caused the same reaction. One year previously he had experienced typical vasomotor rhinitis each time following the drinking of rye whisky. None of these three ingestants produced symptoms prior to or subsequent to these years.

Mr. H. experienced hives after eating tomatoes during the World War and for two years thereafter. Since then he has been able to eat them without reaction, usually eating them about twice daily.

Miss R., aged fifteen, had had hives at age ten for a period of two months attributed to strawberries. She avoided them for a time but can eat them now without difficulty.

Mr. R. experienced urticaria from strawberries in childhood. He eats them now without discomfort.

Mrs. B. found that during one summer watermelon consistently produced vomiting and diarrhea, but since then, she has had no trouble.

Mrs. F. eight years ago found that watermelon produced angioneurotic edema of the hands and tongue. Even the juice of watermelon on the hands produced swelling. Watermelon now causes no symptoms.

Miss W. observed that several years ago strawberries caused abdominal cramps and nausea. She avoided them for several years and this year has taken them without discomfort.

Mrs. M. three years ago had hives in the summer time, cause unexplained. Since then she has had no return.

Mrs. C. experienced eczema in childhood involving the hands only and lasting for three months. This was presumably due to chocolate. She has had no return of trouble until within the last few months when the eating of chocolate produces urticaria and cardiac palpitation, often with headaches. Plums consistently produced diarrhea a year ago: none before or since.

Mrs. B. experienced diarrhea from cut corn in childhood. She eats corn without difficulty now.

Mr. G. several years ago regularly had sour stomach and heartburn from the eating of cucumbers. He now eats them without difficulty.

The transient allergic rarely needs advice or study by the physician. He himself realizes the etiology of his symptoms and cures himself by avoidance. Not all lose their sensitization after a period of avoidance. Not a few report the reappearance of symptoms each time they eat the offending food. This group obtains relief by one of three methods, (a) outgrowing the specific sensitization, (b) continued avoidance, and (c) unconscious incidental changes in their routine by which they unwittingly are removed from the causative

agent. This happens more frequently in inhalant and contact allergy than in food allergy. A lady in her forties had had asthma in childhood which, as she stated, she outgrew. She was sensitive to cat hair and remarked that while they had had cats in the house in childhood she had always despised them and that she had had none for years. She had relieved herself intuitively by avoidance.

MAJOR OR FRANK ALLERGY

The physician is, however, more frequently faced with the problem of determining the offending food in the major or frank allergic.

Here several procedures may be followed. Realizing that the frank allergic is more likely to be sensitive to the foods usually eaten, the staples, the doctor may place his patient on an elimination diet or trial diet from which the common offenders have been deleted.⁴ This would work well were it not that in addition to the staples the chronic allergic is also usually sensitive to one or more of the infrequent offenders, as is the minor allergic. Since these usually show up positive on skin testing, indeed more frequently than do the staple offenders, we find it more logical and more frequently successful to perform preliminary skin testing on the basis of which infrequent and frequent offenders may be promptly eliminated without guesswork. It is quite true that one may be sensitive to an allergen which fails to produce positive skin reaction just as one may show positive skin reaction to an allergen which fails to cause trouble. But in the great majority there is a correlation between positive skin reaction and symptoms. It has been conservatively estimated that skin testing will give only 50 per cent of reliable information on allergenic foods.⁵ But if this procedure diminishes the amount of necessary subsequent work by 50 per cent it is well worth employing and is indeed the foundation procedure for subsequent investigative superstructure.

TESTING METHODS

Sensitization tests may be performed either by the scratch or cutaneous method or by intracutaneous or endermal testing or by passive transfer. The last is only occasionally required, particularly in the study of infants or individuals with such generalized dermatitis that there is not sufficient space for skin testing or in those with a general urticarial tendency in which all tests show up positive. In this event blood is obtained from the patient, the serum is diluted and filtered through porcelain and introduced intracutaneously into the skin of the nonallergic recipient. Later, the recipient is tested in the passively sensitized sites by the intracutaneous method, with control tests applied to areas of his nonsensitized skin.

The customary procedure in the majority of cases, however, is the scratch test and the intracutaneous test. Both have their advantages. The former possesses the advantage of safety with the disadvantage of diminished accuracy. The latter is more sensitive but occasionally dangerous because of its extreme sensitiveness. Both methods should be combined. If one would avoid the rare anaphylactic reaction, one will never do intracutaneous tests without preliminary scratch test. This is our routine procedure. As far as foods are

concerned, scratch tests are first applied with the individual foods. The positive scratch foods are removed from the intracutaneous test boards and the remainder of the series is then repeated with endermal tests. In order to reduce the requisite number of intracutaneous tests, group intracutaneous reactions are obtained, using solutions containing two or more allergens grouped together in accordance with their genetic or biologic relationships.⁶

Where intracutaneous tests are done without preliminary scratch testing, the potentialities for untoward reactions are so great that one must use very dilute intracutaneous solutions. In this case 1/5,000 concentration is usually selected. The intracutaneous test is about 100 times more sensitive than the scratch.⁷ In our own work I use a scratch concentration of 1/50. If in our intracutaneous work we were to use 1/5,000 concentration or 100 times dilution over our scratch reaction, we would find that the intracutaneous test is no more sensitive than the scratch. This is the advantage of preliminary scratch testing. If the scratch reaction has been negative, one can proceed intracutaneously with a solution at least ten times more sensitive. This implies a 1/500 instead of 1/5,000 concentration. As a matter of fact we have no hesitancy in our own work in using 1/250, provided the preliminary scratch test was negative.

In short, if one is using 1/5,000 concentration for intracutaneous testing, this is no more accurate than the scratch method. But if one will use a more concentrated intracutaneous solution after preliminary scratch testing, results will be more accurate due to the finding of an additional number of low grade positive reactions. Intracutaneous extracts in which foods are grouped in accordance with biologic relationships diminish the requisite number of needlings. It is not safe to employ groups in scratch testing since each additional food in the group increases the likelihood of false negative reactions.

As a rule the intracutaneous test will show as positive some of the reactions that were negative by the cutaneous test. However, not infrequently foods and other allergens will show up positive by the scratch method, being at the same time negative intracutaneously. This is another reason why the combination of the two methods promotes greater accuracy.

Assuming that we are dealing with a case of food allergy and that the sensitization studies have shown positive reactions, we will proceed to place the patient on a special diet from which the positive reactors have been eliminated and to which adequate substitutes have been added to provide the requisite food values.

TRIAL DIETS AND THE FOOD DIARY

If, in a food allergic the program fails of results, the next logical step is the trial or the elimination diet.

The diets that have been proposed in the literature are based on the principle that in major allergy foods more frequently eaten are the more frequent offenders, and that these are especially likely to give false negative reactions on skin testing. If one will pay attention to the borderline reaction and the delayed positive, the latter assumption will not be found to be true as often

as is generally believed. But the first assumption is quite valid. Series of alternative elimination diets have therefore been proposed which provide for the elimination of the common ingestants but which do not take into consideration the undoubted fact that the major allergic is usually sensitive to one or more relatively infrequent foods as well as to one or more common foods. And several of the infrequent foods appear on the elimination diets. For this reason I object to the use of the elimination diets without preliminary skin testing. Instead, I prefer my trial diet,³ which, however, must be individualized for each patient. It has a double basis, the elimination of staple foods and, in addition, the avoidance of those foods to which the patient was found on trial to be sensitive. It is built up on a foundation list of foods to which in my experience both groups of patients are infrequently sensitive and to which are added other foods to which the patient has been found by testing to be nonsensitive. Naturally, if the patient has been found sensitive to a member of the foundation list that also is deleted.

There are a few food allergies in whom the offending food cannot even be found after a combination of the sensitization studies and the trial diet. In this case the food diary becomes requisite. It is only of value where the symptoms are intermittent and I have found from experience that it is much more easily followed if the patient is already on a restricted diet such as the trial diet. A list is kept, daily, of all foods eaten as well as of any occurrences out of the usual routine of the day. Days on which symptoms are manifested are checked and a comparison of these checked days with the foods eaten on that day and the preceding day and with the events of these two days occasionally enables one to determine the etiologic factor.

Thus we see that the treatment of the food allergic goes along in a logical sequence based first upon the sensitization reactions, modified as need be by the trial diet, and finally checked, if necessary, with the food diary.

DISCUSSION WITH THE PATIENT

I have omitted discussion of the first and one of the most important procedures of the examination, discussion with the patient. Note that I do not state "taking the history." Discussion with the patient in allergy involves much more than routine history taking. It is because it should follow as well as precede the allergic examination that I discuss it now. Much information can often be obtained from discussion with the patient of his past allergic history prior to the institution of testing, but a surprising amount of additional information is often acquired from a continuation of the discussion after the patient has been made acquainted with the list of positive reactions. This will refresh his memory on many hitherto unremembered incidents of his past experience and will show a surprisingly increased correlation between the positive skin tests and the patient's own experiences. Discussion should include a careful inventory of the family allergic history including not only asthma, hay fever and urticaria but also eczema, sick headaches and food upsets. The same series of maladies should be investigated in the patient. Also symptoms suggestive of allergic indigestion or colitis. One should bear in mind that

the manifestations of allergy are often obscure and bizarre, and one should be on the watch for unusual symptoms which can be fitted into the picture, both at the time of the preliminary questioning and at the final discussion as well as at subsequent follow-up discussions that may be had from time to time. The following cases represent some of the unusual manifestations of food allergy.

A young lady of twenty-four complained of lack of energy. If she stays up as late as 11 o'clock she feels dead the next day. She says she could sleep indefinitely. However, at night she does not sleep soundly. She had had nocturia since childhood. She had had her appendix removed six years previously in an effort to relieve her symptoms and for two months prior to examination she had been fed increasing doses of thyroid. Her metabolic rate had been minus 16 and the asthenia has been ascribed to thyroid deficiency. However, the thyroid intake had been increased to 12 gr. daily with no improvement but with symptoms of thyrotoxicosis, daily diarrhea, trembling, palpitation, nervousness and vertigo.

Discussion with the patient brought out that each year she had a spell of urticaria which she believes is due to strawberries and tomato, that her sister develops a vasomotor rhinitis when near cats, and that her brother sneezes many times each morning when he arises. She gave only borderline reactions to the legumes, chocolate, wheat, banana, and ginger. All medication including thyroid, was discontinued. The foods mentioned were eliminated. Five days later she reported that she had more pep than she had had for months, and now, five months later, she still reports herself full of energy, free from nocturia, sleeping well and relieved of a neuritis that had been bothering her for several months.

Note that she complained of no allergic symptoms. They were brought out only after discussion. The following cases also bring out this point.

A man of thirty-five, complained of a low grade dermatitis of three years' duration, worse in the autumn, of heartburn and constipation, and of easy fatigability. As he said, he awakened tired in the morning and had to drag himself out of bed. He was seeking relief for his indigestion. Discussion with him developed that he had had seasonal hay fever in childhood from age eight to twenty-one and occasional headaches of undetermined origin in childhood. In former years before the development of the chronic heartburn, he had had intermittent attacks of heartburn brought on definitely by cucumber, tomato, and strawberry. He was found sensitive to 14 foods including milk, peas and beans among the staples and apple, pear, peanuts, celery, cantaloupe, cucumber, berries, chocolate, tomato and banana among the occasionals. On dietary restrictions his skin rash, lack of energy and indigestion disappeared, and although he had been obstinately constipated for years, his bowels became regular. Two years later he reported that except for one interval when he had strayed from his diet he remained entirely well.

Miss M., complained of extreme dysmenorrhea and some low grade indefinite indigestion. It was found that she sneezed a great deal. Her hay fever was not sufficiently severe to justify treatment. She knew the cause to be dust. No cause other than a possible allergy was found for her indigestion.

Her chief complaint was dysmenorrhea which she described as intense cramps with sometimes, fainting spells on the first and third days.

She was found sensitive to wheat, cotton seed, corn, and some incidental foods and was advised to avoid these during the week prior to, and through the duration of her period. She did this with relief of pain.

Miss H., also subject to ragweed hay fever, suffered from headache over the left eye, only during the catamenia. She was also found sensitive to certain foods and discovered that by avoiding them during the week prior to and through the catamenia she was relieved of these headaches.

FOOD DISLIKES

It has been suggested that a history of food dislikes suggests a sensitization to the undesired food, that dislike for a food to which the patient is unknowingly sensitive constitutes a protective reaction.⁵ My own experience has been rather the reverse, that most allergies will say that they are very fond of the particular food which is responsible for their symptoms. Only occasionally have I found evidence of a correlation between dislike and sensitization.

In my series of 100 so-called nonallergics, 46 showed evidence of food allergy and 66 expressed food dislikes. Most complained of the taste, some of the appearance, and some explained that they continued to taste them for many hours after eating. The list of foods disliked is altogether different from that of foods causing minor allergic manifestations, and includes, in order of frequency, spinach, turnip, cabbage, carrot, okra, lamb and squash, with a scattering of others (Table I).

Food dislikes as well as food disagreements were usually multiple. In no instance was there entire agreement between foods disliked and foods responsible for symptoms. In four instances one among several foods and in five instances two among several foods corresponded in both groups. We may conclude, therefore, that while dislikes may occasionally be indicative they cannot be relied upon.

There is an old superstition or better tradition that certain combinations of foods which are individually harmless become harmful to certain individuals in an allergic way. This tradition crops out in my series. Whether it is an actual synergism or merely a coincidence remains for future investigation to determine. Combinations mentioned are such as milk and fruit, orange juice and ice cream, cake and cabbage, fish and milk, deviled crab and ice cream. Each of these foods eaten separately caused no reaction nor did the individual constituents of the following special dishes to which symptoms were attributed: crab flake salad, frozen fruit salad, potato salad. In these salads the cotton seed oil presumably present in the salad dressing may have been the responsible factor.

CONCLUSION

I trust that in discussing these many ramifications of the problem of food allergy I have not made it appear discouragingly complex. It is a complex problem which can only be made simple by an adequate understanding of it. The points which I have discussed should enable one to avoid most of the many pitfalls. Too many doctors and patients alike feel that the skin test is the last court and conclude if the results of skin testing fail to relieve, that allergy is not a factor.

I would emphasize particularly the need for frequent follow-ups, particularly in those who are not doing as well as one thinks they might. It is surprising how often new factors are found to crop up. The variability in sensitization from time to time and the factor of interaction with nonspecific causes are chiefly responsible for this. One should bear in mind at all times that the

allergic state is never static. It is intimately bound up with the problem of nutrition and indeed with the biochemical activities of the process of life itself. Representing as it does changing responses to a changing environment it is not at all surprising that supervision must often be continued over a prolonged period before all factors are finally brought under adequate control.

808 PROFESSIONAL BUILDING

THE INACTIVATION OF GROWTH HORMONE*

AS A RESULT OF INADEQUATE REFRIGERATION

H. S. RUBINSTEIN, M.D., BALTIMORE, MD.

IN CARRYING out experiments dealing with the brain weight-body weight ratio¹ it became necessary to use anterior pituitary extracts as growth stimulators. In the course of this work it was found that while fresh extracts possessed this quality, the effect was lost when refrigeration was inadequate. It is the purpose of this communication to report on the inactivation of growth hormone as experienced in this laboratory. An extract of the anterior lobe of the pituitary gland was prepared by a modification of the Putnam, Teel and Benedict² technic so that 2 c.c. of the final product represented one gram of the fresh anterior lobe. Such extract when used *fresh* showed a definite growth-stimulating effect.¹ When ready for use as fresh extract this preparation was distinctly alkaline to phenolphthalein and possessed a P_H of 8.3.

Twenty-one adult female white rats (*Mus norvegicus albinus*) were used in these experiments and these were arranged so that only litter mates were used as controls. Litters were used which contained four or five females of which two received growth hormone, one received no injections, and the remaining one or two, injections of meat extract.

*From the Neuro-Anatomical Laboratory, Department of Anatomy, University of Maryland, School of Medicine.

Received for publication, November 5, 1932.

Upon intraperitoneal administration of this extract in the dosage of 2 c.c. daily (except Sunday) growth effects became quite noticeable. The controls injected with meat extract and those uninjected failed to increase in size.

It was found, however, that after a growth increase for two or three weeks the rats injected with the same preparation began to lose weight. A fresh extract, alkaline in reaction, was substituted and the next week the animals again gained weight. This weight increase and subsequent weight loss was noted repeatedly showing that the growth-stimulating effect of the extract used was lost after two or three weeks (Chart I).

A study of the inactivated extract revealed that its alkalinity had decreased to such an extent that it was no longer alkaline to phenolphthalein.

Chart I.

One of the animal groups which had reacted alternately by growth increase and weight loss was then subdivided into two. To one of these the acidified extract was continued; to the other, a fresh alkaline preparation was administered (Chart II).

It was noted that the animal receiving fresh extract again gained weight while the animal which was continued on acidified extract failed to show any gain. Some of the animals receiving acidified extract actually lost weight after a previous increase had been noted (Charts I and II). It was also found that the addition of sufficient alkali to restore the original P_H after acidity had occurred failed to restore the potency of the extract. This failure was to be expected, since if addition of alkali to acidified extract could restore

potency, the buffers of the blood should be sufficient to produce this alkalinity and growth would be obtained even after acidity had occurred.

In order to prevent the use of inactivated (acidic to phenolphthalein) extract, it was found advantageous to add an indicator to the growth hormone preparation. Accordingly, two drops of a 1 per cent alcoholic phenolphthalein solution were added to each 30 c.c. of the pituitary extract and preparations were used only as long as they retained a pinkish tinge.

Where an extract is made and immediately placed on ice, its potency lasts for several months, but where refrigeration is imperfect as in those instances where the extract has to be shipped it appears that an indicator is of value.

Chart II.

SUMMARY

1. Alkaline extracts of the anterior pituitary gland become less alkaline as a result of imperfect refrigeration.
2. This decreased alkalinity inactivates the growth hormone.
3. Adequate refrigeration decreases the rapidity of inactivation.
4. The adjustment of P_H after inactivation, fails to restore the potency of the extract.
5. Phenolphthalein added as an indicator serves as an index to the alkalinity of the preparation which must be maintained if the extract is to remain potent.

The author is greatly indebted to Dr. Carl L. Davis, head of this Department, at whose suggestion this paper was written.

THE TREATMENT OF BRONCHOPULMONARY SUPPURATION OF FUSOSPIROCHETAL ETIOLOGY WITH SMALL DOSES OF NEOSALVARSAN*†

H. I. SPECTOR, M.D., ST. LOUIS, MO.

FUSOSPIROCHETOSIS is gradually gaining recognition as an important factor in bronchopulmonary pathology. Receiving its first clinical recognition in Ceylon, India, in 1906, by Castellani,¹ who described it under the name of "bronchopulmonary spirochetosis," it has, through its cosmopolitan character, gained the attention of clinicians the world over.

It is with the hope of stimulating further study in regard to treatment of this deserving subject, that an attempt is made to relate the experiences gained from a study of 25 cases of acute and chronic bronchopulmonary suppuration in whose sputum, spirochetes, fusiform bacilli, vibrios, and other anaerobic organisms were repeatedly found.

To begin with, it should be stated that about 80 per cent of normal mouths and practically all pyorrheic mouths harbor anaerobic organisms, particularly spirochetes. These organisms are found about the teeth, tonsils, and adenoids, as pointed out by Davis and Pilot,² Carpenter,³ and others.

That the buccal anaerobes may produce serious diseases was called to our attention by Plant⁴ in 1894 and Vincent⁵ in 1896 when they pointed out the relationship of these organisms to Vincent's angina. That aspiration of oral contents into the lungs can easily take place has been demonstrated in animal experiments by Kline,⁶ Smith,⁷ Crowe and Scarff,⁸ Allen,⁹ Hedblom, Joannides and Rosenthal,¹⁰ Harkavy,¹¹ Schlueter and Weidlein,¹² Bethune,¹³ and clinically, by Myerson,¹⁴ Daily and Daily,¹⁵ Iglauer,¹⁶ and Ochsner.¹⁷

There has been considerable discussion as to whether or not the aspirated mouth organisms are merely saprophytic contaminants of the tracheobronchial tree or actual pathogens. There is a growing belief that a previous pyogenic infection may prepare the way for the action of the anaerobes in symbiosis and contribute to the pathogenicity of the lesion.

Predisposing factors of bronchopulmonary spirochetosis are poor hygiene of mouth, such as pyorrhea alveolaris, carious teeth, infected tonsils and ade-

†Read before the St. Louis Medical Society, February 2, 1932.

noids, infected sinuses, and Vincent's angina. Operations on the upper respiratory tract or operations in general under deep anesthesia may predispose to the development of the condition. General debilitating diseases such as diabetes, pulmonary tuberculosis and cancer may be associated with the condition. The existence of previous bronchopulmonary pathology such as chronic bronchitis and emphysema, bronchiectasis, and chronic fibrosis of the lungs in general, may predispose to the development of bronchopulmonary spirochetosis.

TREATMENT

From the preceding discussion it is evident that mouth hygiene is one of the indispensable measures in the prophylactic control of this condition. Carpenter³ states that patients without teeth and tonsils only occasionally harbor spirilla, and suggests the thought that to eradicate fusospirochetal diseases from the human race, we must remove all teeth, tonsils, and adenoids.

A review of the literature reveals the following general procedures available for the treatment of acute and chronic suppuration of the lung: (a) Prolonged bed rest, (b) bronchoscopy, (c) pneumothorax, (d) oleothorax, (e) phrenicoectomy, (f) incision and drainage, (g) thoracoplasty (partial or complete), (h) lobectomy and cauter pneumectomy, (i) heliotherapy, (j) transfusions, (k) vaccine therapy, and (l) medicinal measures.

A study of the literature reveals that many drugs have been recommended for the treatment of this condition, such as tartar emetic, iodine, antimony, emetine, bismuth, and the various arsenicals such as sulpharsphenamine, salvarsan, and neosalvarsan. Vincent¹⁸ also reported the use of a serum for the treatment of gangrene.

It is the purpose of this paper to limit the discussion to the value of the arsenicals in general and neoarsphenamine in particular in the treatment of suppuration of the lungs of fusospirochetal origin.

It is amazing to find that until very recently most writers actually failed to mention the arsenicals in their discussion of treatment of suppuration of the lungs.

Due to the accumulation of evidence strongly pointing to the potential pathogenicity of the mouth organisms, and due to the possibility that the various forms of acute and chronic suppuration of the lungs may merely represent different phases of the disease fusospirochetosis,¹⁹ more attention is being given to the drug. Some physicians believe in its specificity, others fail to see any value in its use. On the one hand, we find Kline and Berger²⁰ who state, "Arsphenamine therapy is apparently as specific in this as in other spirochetal infections." On the other hand there is Miller²¹ who states, "Specific therapy, particularly arsphenamine, is by no means regularly successful. In fact, in my experience, it rarely has proved to be of real specific value."

Why these opposing views, is a question that immediately confronts one and tempts one to speculate for a possible answer. It is interesting to note in this connection that to date one fails to find in the available literature any scientific discussion of dosages, frequency of administration, and reasons for favorable or unfavorable results in the treatment of suppuration with arseni-

cals. Some writers merely mention the drug without qualifying the dose; others content themselves with the statement that the dosages used are the same as in syphilis; while still others advocate intensive doses such as 0.6 to 0.9 of a gram of neosalvarsan.²⁰

The value of large doses of arsenicals in the treatment of suppuration was first questioned by me²² about three years ago when neosalvarsan was used by me in two cases of abscesses complicated by gangrene. The initial dose used in each patient was 0.3 gm. In each instance unfavorable reactions followed the administration of the drug; the temperature rose to a higher level, dyspnea was more marked, and the sputum became more foul. Both patients gradually became worse and died within a few days. The opportunity to investigate the possible value of small doses of neosalvarsan in the treatment of this condition did not present itself until October, 1930,

Fig. 1.

when three of the patients with acute suppuration of the lungs failed to show improvement, and were definitely worse after a reasonable time of treatment with conservative measures. However, before instituting radical treatment which seemed almost compelling, it was decided as a last conservative measure, to use neosalvarsan in small doses.

To evaluate properly the results obtained with this drug in small doses curtailed case histories of the three patients will be helpful.

CASE 1.—L. P., white boy, thirteen years of age, admitted to St. Mary's Infirmary (a part of St. Louis University group of hospitals) on Sept. 29, 1930, six days following the removal of his tonsils and adenoids under general anesthesia. On September 27 he had a sudden severe pain in left chest region, followed by fever, cough, and vomiting. On the day of admittance, the sputum became slightly foul. The white count was 8200, red count, 4,525,000, and hemoglobin 90 per cent. The temperature was 103°, pulse 120, and respirations 28. Sputum was negative for T.B., positive for elastic tissue, and sputum culture re-

vealed pneumococci, streptococci, *Micrococcus catarrhalis*, and a gram-negative rod. There was a marked shift to the left with the Arneht Schilling method.²³ The blood sedimentation rate²⁴ was rapid and the Wassermann was negative. Physical examination revealed dullness and diminution of breath sounds and inconstant posttussive clicks in region of left apex. A diagnosis of lung abscess was made which was confirmed by a roentgenogram (Fig. 1).

Fig. 2.

Fig. 3.

The patient was treated conservatively with bed rest, postural drainage, and symptomatic treatment. However, in spite of this treatment he became definitely worse. On the twelfth day after admittance, the sputum assumed a grayish greenish appearance, became definitely bloody, and very offensive in character. The temperature at this time was 104°, pulse 146, and respirations 48, and the white count rose from 20,100 on the twelfth of October to 33,800 on the sixteenth of October. At this time the patient was also having a hemorrhage. A diagnosis of beginning gangrene was made. On the twenty-seventh of October a dark-field examination of the sputum revealed numerous spirochetes. On the twenty-eighth of

October, four weeks after admittance, he was given 0.05 of a gram of neosalvarsan intravenously, and twenty-four hours afterward, there was a drop in fever to 101° and in forty-eight hours to 99° as seen in Fig. 2. With this drop in fever general improvement was noticed. The sputum diminished in quantity and was no longer foul. Patient was given 0.1 gm. of neosalvarsan on the first and fourth of November, 1930, and was discharged on

Fig. 4.

Fig. 5.

Jan. 2, 1931 very much improved. He was observed in the chest clinic until cured as seen in roentgenogram (Fig. 3). A reexamination on Jan. 7, 1932 revealed that the patient remained well.

CASE 2.—P. L., white male, aged twenty-six, admitted to hospital on Oct. 10, 1930 complaining of pain in right chest region, cough, loss of weight, tired feeling, fever, and

sweats, all these symptoms having been present since onset four weeks prior to his entrance into the hospital. He noticed no improvement while at home despite the fact that he was kept at complete bed rest. Temperature at entrance was 101° , pulse 120, respirations 24, W.B.C. 12,400, R.B.C. 4,830,000, hemoglobin 88 per cent. Arueth Schilling count showed a marked shift to the left. Sedimentation rate was rapid. Nonprotein nitrogen 29, blood sugar 98, Wassermann negative, urine negative, sputum negative for T.B., but revealed streptococci, pneumococci, *Micrococcus catarrhalis*, and gram-negative rods. Physical examination revealed definite limitation of motion on the right side, dullness and diminution of breath sounds and scattered indefinite râles from the fourth vertebral spine to base of right lung posteriorly. A roentgenogram (Fig. 4) showed an increase in density at base of right lung. A diagnosis of suppurative pneumonitis was made.

Patient was at first treated conservatively, but no improvement was noted after twenty-five days of such treatment. The afternoon temperature varied from 101° to 102° , pulse 100 to 120, and respirations 24 to 30. A roentgenogram showed a definite extension of

Fig. 6.

the process. Repeated dark-field examinations of sputum at this time revealed fusiform bacilli. On Nov. 5, 1930, twenty-five days after admittance, he was given 0.15 gm. neosalvarsan and within twenty-five hours, subjective improvement was noticed and also a temporary drop in the fever to 99.6° . Three-tenths grams of neosalvarsan was then given on Nov. 9, 1930, after which time the temperature again dropped temporarily to 100° as seen in Fig. 5. On November 22, thirteen days after, the second dose, 0.45 gm. of neosalvarsan was given after which time the temperature dropped to normal and the patient improved steadily to complete recovery as seen in Fig. 6.

CASE 3.—R. D., white female, aged twenty-seven, admitted to hospital on Nov. 3, 1930 with the following complaints: Weakness, loss of strength, pains in chest and lumbar region, chills and fever, shortness of breath. She was delivered of a baby two months prior to her entrance. A month following delivery she began to have chills followed by fever. Two weeks before entrance she began to have daily chills. Her physician diagnosed her condition as malaria, and she was treated for this condition. Failing to improve, she entered the hospital. Temperature varied from 97° in A.M. to 105.8° in P.M., pulse, from 90 to 130,

and respirations, from 20 to 28. W.B.C. 11,500, R.B.C. 3,470,000. Hemoglobin 85 per cent. Urine (noncatheterized) specimen showed 2-plus albumin, and a few pus cells. Catheterized specimen showed urine to be negative. Urine culture was negative. A Schilling count showed

Fig. 7.

Fig. 8.

a shift to left and was negative for malarial parasites. Wassermann was negative. Non-protein nitrogen was 29. Blood sugar was 91. Blood culture was negative. Stools revealed a yeastlike organism. Sputum showed numerous spirochetes and fusiform bacilli with the carbolfuchsin stain. Physical examination revealed the essential pathology to be in the

chest as follows: Dullness on percussion in lower one-third of both lungs, but especially on the left side. Harsh breath sounds in lower half of both lungs especially pronounced on left side. Scattered fine posttussive râles in lower half of both lungs. Bronchial breathing opposite sixth vertebral spine on the left side. Gynecologic examination by the gynecologic department failed to reveal any pathology in the pelvis to explain the chills and fever. A roentgenogram (Fig. 7) revealed a small area of density at base of left lung close to heart

Fig. 9.—Anaerobes from a spirochetel empyema.

Fig. 10.—Anaerobes from the sputum of a case of spirochetel abscess.

and one suspicious shadow in second interspace. A diagnosis of multiple lung abscesses seemed to be justifiable under the circumstances.

Patient was treated for possible pyelitis with no results. Neosalvarsan was given 0.15 gm. on November 10, and temperature dropped to 102° the next day; the chills did not recur. In forty-eight hours the temperature dropped to 100°. Two-tenths gram was given on November 15, five days after first dose, and temperature dropped to normal the next day and remained normal as seen in Fig. 8. Clinical improvement was very rapid. Patient made a complete recovery later. In answer to a follow-up letter that was sent to her on Jan. 2, 1932, she stated that she had remained well.

to large doses. The report of the Salvarsan Council of Great Britain³⁰ and the recent article by Cole³¹ and coworkers definitely points to the fact that accidents in the treatment of syphilis are most common when large doses are used.

The most important proof in favor of small doses, however, is the experimental work of Toyama and Kolmer³² who have shown that large doses of either arsphenamine or mercury directly interfere with the nonspecific defense, and diminish the production of agglutinins and lysins with which the body carries on its own defense against the invader. On the other hand, minute doses have a definitely stimulating effect on the patient and seem to encourage the formation of agglutinins and lysins.

In summarizing the possible action of small doses of neosalvarsan in the treatment of fusospirochetosis, it is conceivable that the salvarsan, through its specific spirillicidal action, kills the spirochetes, and through its nonspecific tonic action stimulates the formation of agglutinins and lysins which in turn destroy the other members of the symbiotic group.

I am greatly indebted to Dr. G. O. Broun, Dr. R. Kinsella and Miss E. McGarry for their assistance and encouragement in this work.

UNIVERSITY CLUB BUILDING

THE GROWTH OF PATHOGENIC BACTERIA IN IMMUNE BLOOD*

FREDERICK W. SHAW, M.D., RICHMOND, VA.

WHEN one consults a text on the cultivation of pathogenic microorganisms from the blood stream, it is generally stated that the procedure consists of withdrawing from 10 to 20 c.c. of blood from a vein and injecting this into 50 to 100 c.c. of broth culture medium, and that this large quantity of culture medium is necessary to dilute the antibodies in the serum, the antibodies being bactericidal. The directions, also, generally state that 5 c.c. of blood may be added to 10 c.c. of melted agar culture medium and plated. Other procedures may call for the addition of the blood to citrated or bile culture medium, the addition of these agents to the broth culture being to destroy the bactericidal action of the blood, particularly the serum. Stitt¹ gives the following technic: "As a receptacle for the blood we employ Erlenmeyer flasks of 100 c.c. capacity, containing 10 to 25 c.c. of salt solution with 1 or 2 per cent of sodium citrate, for prevention of coagulation. In this way we may take from 10 to 25 c.c. of blood. For plates add 2 or 3 c.c. of this citrated blood to 6 or 8 c.c. of melted agar at 45° C. Finally we place the receiving flask in the incubator and culture it as well as the other media. Some organisms do not develop in this citrated blood, possibly on account of the blood concentration. This can be avoided by adding 50 to 75 c.c. of bouillon to the citrated blood remaining in the flask. For culturing blood in septicemic conditions use at least ten times as much bouillon as blood."

*From Department of Bacteriology and Parasitology Medical College of Virginia. Received for publication, December 1, 1932.

Muir and Ritchie² state: "In making blood cultures in order to detect the presence of enteric bacilli 5 c.c. of blood are added to 10 c.c. of sterilized ox bile or 50 c.c. of a 0.5 per cent solution of bile salts in 1 per cent sodium citrate. In examining for other organisms, e.g., streptococci, 5 or 10 c.c. of blood are added to a large quantity of fluid medium (100 c.c. or more)."

Clawson³ draws 50 c.c. of blood and distributes this in two tubes and allows the blood to clot. The serum is withdrawn and the clot removed to 250 c.c. of dextrose beef infusion broth. He states that the firm clot seems to favor a partial anaerobic culture, and at the same time any antibodies that may be present are diluted in the fluid medium.

Cecil, et al.⁴ withdraw 20 c.c. of blood and divide into two tubes. After the clot has formed the serum is withdrawn, the clot broken and transferred to 50 c.c. of beef heart infusion broth. This procedure is used to rid the culture of antibodies.

Mesnil⁵ reported, in 1898, that the serum of rabbits which had been immunized against *Bacterium erysipclatis suum* makes an excellent medium for the culture of this microorganism.

Bridré and Jouan⁶ showed that the observation of Mesnil was also true in regard to horses, and that the *Bact. erysipclatis suum* grew better in the immune serum than in the serum of normal horses. These authors found that the growth in the bouillon which contained the immune serum (10 to 20 per cent) was about six times as great as that containing an equal amount of normal horse serum.

This phenomenon was studied by Nicolle and Césari.⁷ These authors found that the best culture medium was one made of Martin's bouillon 9 parts and immune serum one part. The organisms studied were anthrax, tetanus, gonococcus, diphtheria, typhosus, paratyphosus A, and pneumococcus Types I, II and III. All of these bacteria grew more abundantly in the medium containing the homologous immune serum. The growths of the gonococcus and the pneumococcus were not as readily apparent as the growths of the other microbes, but there was some better growth in the medium containing the immune serum. Some of the organisms grew so abundantly as to form a scum on the surface of the medium; such does not occur in the ordinary culture media.

The phenomenon that concentrated immune serum is not bactericidal in vitro has been known for years. This is called the "phenomenon of Neisser and Wechsberg." These authors found that there was no bactericidal action on the typhoid bacillus when the typhoid immune serum was added to an equal amount of a typhoid culture, but that there was a bactericidal effect when the immune serum was diluted, and that this effect was lost when the dilution reached a certain figure.

Relative to this phenomenon Muir and Ritchie,² page 209, state: "It is to be noted that in the case of a bactericidal serum there is an optimum amount of immune-body which gives the greatest bactericidal effect with a given amount of complement. If this amount of immune-body be exceeded, the bactericidal action becomes diminished and may be practically annulled. This

result, which is generally known as the 'Neisser-Wechsberg phenomenon,' has been the subject of much controversy, and cannot yet be said to be satisfactorily explained; it is apparently of the nature of a 'zone phenomenon.' "

Bolton⁸ found that normal serum may kill relatively more bacteria when diluted than when undiluted.

Neisser and Wechsberg⁹ state that if the immune serum be greatly diluted its action is changed and it loses its general bactericidal power and develops a marked increase in the destructive action upon the homologous organism.

EXPERIMENTAL

In order to test out some of the above statements rabbits were immunized with *B. typhosus*, *B. abortus*, and a streptococcus. The titers of these sera were 1:6400, 1:3200, and 1:100 respectively. The sterile sera were placed in sterile tubes and inoculated with the homologous organism. The growth was profuse in all of the cultures. Blood was also withdrawn from each rabbit and defibrinated by the use of a sterile Erlenmeyer flask which contained broken glass; a separate flask was used for each rabbit. Each defibrinated blood was inoculated with its homologous organism. The organisms grew abundantly in these media.

The blood serum of a patient having a titer of 1:25000 for *B. typhosus* was available, at this time, as was the organism isolated from the patient. The undiluted sterile serum was inoculated with the homologous organism. The organism grew so abundantly that it formed a scum on the surface of the medium. The growth was so rank in the three tubes which were used that it was at first thought that the serum was contaminated. This experiment was repeated with other strains of *B. typhosus* and the same phenomenon occurred. Other cases of typhoid fever became available as time went on and this same procedure was followed with the same results.

It was decided to apply the above facts to the isolation of microorganisms from the blood stream, i.e., blood cultures. The technic consisted of withdrawing 20 c.c. of blood and discharging 5 c.c. into each of two culture flasks containing 50 c.c. of veal heart infusion broth, and the remaining 10 c.c. were discharged into an Erlenmeyer flask of 50 c.c. capacity containing broken glass (glass beads may be used) to defibrinate the blood. In several experiments a 100 c.c. flask was used and 20 c.c. of blood placed in the flask. The flask containing the defibrinated blood was placed in the thermostat like any other culture. The flasks were examined and transplants made as usual.

It is apparent that there are but a given number of bacteria per cubic centimeter of blood in a blood stream infection, and in carrying out an investigation with standard methods for controls it is possible that the bacteria may be present only in the blood discharged into the defibrinating flask; it is likewise possible for the organism to be discharged from the syringe only into one of the flasks containing the broth; however, no culture, to date, has been obtained in the broth and not in the defibrinated blood, while the reverse has occurred on a number of occasions.

The following organisms have been isolated from the blood stream by the defibrinated blood technic: *B. typhosus*, *B. paratyphosus* B, *B. abortus*, gonococcus, *M. catarrhalis*, and streptococcus.

COMMENT

The literature on the methods of taking blood cultures assumes that whole blood is bactericidal, due to the serum. The work of Neisser and Wechsberg shows that this is not the case. This is further substantiated by the work of Nicolle and Césari who found that the immune serum stimulated the growth of the homologous organism. It appears to me that it is but logical to assume that such would be the case, inasmuch as the infecting agent is living in the blood stream, or at least in the tissues served by the blood, and that in vivo, at least, this makes a most excellent medium; a better medium, perhaps, than the blood of a normal animal, or individual in the case of human beings. The above experiments seem to bear out this assumption.

The work of some investigators would indicate that the bactericidal zone of the serum is that in which most of the cultures are diluted in the standard methods. Due to the number of positive cultures obtained in this zone, it appears that the bactericidal zone varies widely.

The use of defibrinating flasks for blood cultures simplifies the taking of these cultures and gives a satisfactory medium for the infecting organism. The defibrinated blood may be covered with a layer of oil for the cultivation of anaerobes, although, experimentally, anaerobes were grown in the defibrinated blood without oil by using a small flask and withdrawing an extra amount of blood to give extra depth of medium for anaerobic conditions.

LABORATORY METHODS

AN AUTOMATIC AND GRAPHIC METHOD OF RECORDING DIURESIS*

W. E. GOWER, CHICAGO, ILL., AND J. VAN DE ERVE, CHARLESTON, S. C.

IN CONNECTION with experiments on the relationship of diuresis to recovery from barbital poisoning reported elsewhere by us,¹ we looked about for a suitable method for recording the rate of urine flow from barbitalized dogs over an extended portion of the recovery period. The nature of the experiments was such that it was necessary to know whether a given urine volume collected over an eight- to twenty-four-hour period represented uniform renal

Fig. 1.—Apparatus for recording the rate of urine output. For explanation see text.

performance over the entire period or an increasing, decreasing, or fluctuating rate of flow. To suit our needs the record should be condensed, graphic, continuous, and automatic to the extent of not requiring constant or even exactly periodic attention on the part of the laboratory staff, and should permit fairly accurate calculation of the rate of flow for any increment of time. None of the existing devices with which we became familiar answered these requirements and the success of the method to be described was sufficient, perhaps, to warrant description.

*From the laboratories of Physiology of the Medical College of the State of South Carolina and the University of Chicago.

Received for publication, December 20, 1932.

The female dogs used in these experiments were prepared by perineorrhaphy so that the urethra was easily accessible for catheterization. In most of the experiments barbitol anesthesia was obtained before the records were started, but a few records were made in nonanesthetized animals trained to lie quietly and submit to the administration of fluids and diuretic or anti-

Fig. 2. (See legend on opposite page.)

diuretic principles. Under the experimental conditions the rates of urine flow varied from less than 2 to over 60 c.c. of urine per kilogram per hour in animals weighing from 5 to 20 kg.

In principle, the method consists of collecting the urine through a retention catheter adjusted in the bladder into a cylinder containing a float, the rise of which is recorded by means of a suitable lever system and writing point on a smoked drum moving about $2\frac{1}{2}$ cm. per hour. At the top of the excursion the cylinder is automatically emptied, returning the writing point to the base line for another trip.

The method allows of considerable variation and refinement. Our arrangement is diagrammed in Fig. 1, showing three upright parallel cylinders with communication at their bases, one for receiving the urine, one for operating the float, and a third for emptying the apparatus intermittently by siphon. Each excursion represents approximately 35 c.c. of urine. For clearness of illustration it is represented as being an all glass one piece apparatus; actually it was assembled by means of T-tubes, rubber tubing and glassware as found in the average laboratory.

In the use of the apparatus the greatest technical difficulty encountered is in the adjustment of the siphon to empty the cylinders with uniform excursions and urine volumes, and an electromechanical arrangement may eventually prove more satisfactory. The tendency for a few drops of liquid to become dispersed along the siphon tube and by their weight cause premature emptying, is reduced by extending the siphon tube with a larger glass or rubber extension to a flask several feet below the level of the table or on the floor. This extension accelerates the emptying process by the greater pull of the longer liquid column, draws fewer interspersed drops of fluid into the constricted upper portion of the siphon tube, and those lodging in the expanded portion drain down the walls of the tube establishing an air column without tendency to start the emptying mechanism. Before each experiment we have found it best to adjust the writing point to the newly smoked drum, and by introducing water into the apparatus, produce several satisfactory excursions before starting the record.

Three typical records of urine flow are shown in Fig. 2. These experiments are discussed in the paper previously referred to. Occasional right angle steps in the urine records are artefacts due to imperfect adjustment of

A STUDY OF THE EAGLE ANTIGENS FOR WASSERMANN AND FLOCCULATION TESTS*

THURMAN B. RICE, A.M., M.D., AND VIRGINIA P. SMITH, B.S., M.A.,
INDIANAPOLIS, IND.

THE history of the serology of syphilis is rich in its variety of antigens. Ever since the introduction of an alcoholic extract of normal tissues¹ as an antigen for complement fixation in syphilis, numerous variations of this basic extract have been suggested to produce a more satisfactory and more sensitive antigen. If one could disregard the possibility of false positive reactions due to its intense anticomplementary action, a highly sensitive antigen could be prepared with comparative ease. To insure a margin of safety from false positive fixations, it has been our practice to use only antigens whose antigenic units (the minimum amount of antigen which will produce complete inhibition of hemolysis in the presence of known four-plus sera) are not more than $\frac{1}{100}$ of the anticomplementary unit for that antigen (minimum amount of antigen producing inhibition of hemolysis in the absence of positive sera).

As a routine antigen for the Wassermann test, we use the Kolmer antigen prepared from a cholesterinized alcoholic extract of powdered beef heart.² Each specimen of blood serum submitted to our laboratories for serum diagnosis of syphilis is tested by both Kahn and Kline precipitin methods in addition to the Wassermann test. Although we occasionally find a serum which is positive in a Wassermann test and negative in the precipitin test, generally speaking the precipitin reactions appear more sensitive than the Wassermann reaction. The hemolytic system for the Wassermann test is adjusted to maximum sensitivity and a margin of elasticity allowed for by using two units of complement and two units of amboceptor. These units are determined by graded titrations of the two reagents, using as a unit the smallest amount producing complete hemolysis after one-half hour at 37.5° C.

In November, 1930, Eagle of Johns Hopkins University Laboratories published a paper³ explaining the fortifying effect of cholesterol upon antigens

*From the Department of Pathology and Bacteriology, Indiana University School of Medicine, and Laboratory of Bacteriology and Pathology, Indiana State Board of Health.

used in serum diagnosis of syphilis. Subsequent to this (May, 1931) he published another paper¹ describing a more sensitive antigen for use in the Wassermann reaction. In May, 1932, the same author published a paper² describing the new flocculation test for syphilis.

In our laboratory, under the guidance of the senior author, there was made a study of the comparative values of the Eagle and Kolmer Wassermann antigens, and the Eagle, Kahn, and Kline precipitin tests.

The Kolmer antigen for Wassermann tests is somewhat tedious to prepare and not infrequently freshly prepared Kolmer antigens must be discarded because of insufficient antigenic property or too great anticomplementary activity. Eagle's Wassermann antigen is quite simple to prepare, and to date the authors have had no unsatisfactory lots of antigen prepared by this method.⁴ The increased sensitivity of this antigen is dependent on a high concentration of antigen-lipoids reinforced by 0.8 per cent cholesterolin and 0.6 per cent sitosterol.

Wassermann Technic.—To 0.1 c.c. of freshly inactivated blood serum is added 0.4 c.c. of Reagent A (ten units of antigen and two units of complement in 0.9 per cent NaCl). To a second tube containing 0.1 c.c. of the same serum is added 0.4 c.c. of Reagent B (two units of complement in 0.9 per cent NaCl). Control tubes containing 0.1 c.c. of 0.9 per cent NaCl and 0.4 c.c. of Reagents A and B respectively are placed in the rack with the sera to be tested. These are incubated for two hours at 8° C. To each tube is added 0.5 c.c. of 2 per cent sensitized cells (sensitized immediately before use) containing two units of amboceptor. The tests are then incubated in the water-bath at 37.5° C. until the two reagent controls are completely hemolysed and are left in the water-bath for ten additional minutes before reading. Although Eagle recommends the use of 0.2 c.c. of a 1-200 dilution of antigen without titration, in accordance with our customary procedure we titrated the antigen and used ten antigenic units as a dose.

From our serologic work we tested 1081 cases taken at random, giving no consideration to the case histories before testing. Each of these was tested by Kline's precipitin test, by Kahn's precipitin test (using one quantity of antigen only, 0.025 c.c.) and by Wassermann tests using Kolmer's and Eagle's antigens respectively, and the technic described above. Of the 1081 cases tested, 458 were positive by Kline's test, 346 were positive by Wassermann employing Eagle's antigen, 325 were positive by Kahn's test and 266 were positive by the Wassermann employing Kolmer's antigen. There were no positive K.A.W. (Kolmer antigen Wassermanns) unaccompanied by other positive serology (Kahn, Kline, or Eagle). Likewise there was only one positive Kahn in the absence of other positive serology; this was a treatment check case. Of the Klines, there were 66 positives with no other positive serology. Of these 58 were one-plus (one-plus reactions in any one test unaccompanied by other positive serology are not customarily reported by our laboratory), and 8 were higher positives. Their case histories were as shown in Table I.

TABLE I

	DIAGNOSIS	TREATMENT CHECK	NO HISTORY ON CARD
3-plus	1	1	1
2-plus	0	2	3
1-plus	25	9	24

There were 12 E.A.W. (Eagle antigen Wassermanns) which gave a one-plus reading in the absence of any other positive serology, and 9 higher positives distributed as shown in Table II.

TABLE II

	DIAGNOSIS	TREATMENT CHECK	NO HISTORY ON CARD
4-plus	0	1	1
3-plus	1	1	0
2-plus	3	1	1
1-plus	6	3	3

These results seemed to indicate a sensitivity of the E.A.W. approximately 1.3 times that of the K.A.W., with only a small percentage (21 out of 1081 tests) pointing to possible false positives. There were 325 E.A.W. accompanied by other positive serology, and 324 Kahn tests accompanied by other positive serology. The Kline test was somewhat more sensitive, having 400 positives accompanied by other positive serology. The specificity of these tests could not accurately be estimated by the above method of case selection, due to the fact that many of these cases were only submitted for a single examination and in most cases accompanied by very inadequate history. We therefore selected a number of known syphilitics from the skin clinics of the Indianapolis City Hospital and Fort Benjamin Harrison Hospital.

The ideal type of case would have been those showing early primary lesions, but these cases present themselves very infrequently. From the group of patients in the City Hospital clinics, we were able to secure only three primary cases. One of these, C.P., had been dark-field positive and serologically negative. After three treatments we tested his blood with the following results: K.A.W. four-plus, E.A.W. four-plus, Kahn negative, and Kline negative. A recheck four days later showed K.A.W. two-plus, E.A.W. three-plus, Kahn negative, and Kline negative. This was one of the rare cases in which there appears a greater affinity for the complement fixation phenomena than for the flocculation phenomena. A second case was that of G.A., dark-field positive and with the following serologic findings: K.A.W. negative, Kahn negative, Kline negative, and E.A.W. three-plus. A quantitative E.A.W. (0.1 c.c., 0.05 c.c., 0.025 c.c., and 0.005 c.c. respectively) read three-plus, three-plus, two-plus, and two-plus. A third patient, C.S., having a positive dark-field had the following serology: K.A.W. two-plus, E.A.W. two-plus, Kahn three-plus, and Kline two-plus.

We tested four cases of primary syphilis from Fort Benjamin Harrison. All four had been diagnosed on positive dark-fields and immediate treatment instituted. Two separate testings twelve days apart revealed no positive serology.

Thirty-six "treatment check" cases were tested serologically. The results are tabulated in Table III.

The above results show a close coincidence between the E.A.W. and the precipitin tests. The figures in Table III show a sensitivity of the E.A.W. 3.5 times as great as that of K.A.W. Cases 5 and 26 are the only incidences of a positive E.A.W. in the absence of all other positive serology. The latter developed positives in all three other tests after an interval of fourteen days. The senior author had suggested the possibility that the antigen might prove so sensitive that it would hold a positive indefinitely in treated cases. It was with this possibility in mind that the above series of treated cases was tested, and from the results of this series, we believe we can state that such is not the case. As a further check on this point we ran all four tests on 74 treatment check cases showing completely negative serology by our routine tests. Two of these gave a 1-plus E.A.W., one a 2-plus, and one a 4-plus E.A.W. The others were negative by this test also. Twenty normal individuals were tested by all four serologic procedures and were all negative in every test.

CONCLUSIONS

After having submitted the Eagle Wassermann antigen to the test routine described above, we are convinced that it is a more sensitive antigen than the Kolmer antigen, and that tests in which this antigen is employed correspond very closely to the Kahn and Kline precipitin tests in degree of sensitivity. We believe that in this series of tests it has not proved too sensitive.

THE EAGLE FLOCCULATION TEST

An antigen for this test was prepared according to Dr. Eagle's directions⁵ and one thousand sera treated in the manner he described; K.A.W., Kahn, and Kline tests were done on each specimen. Strong positives and negatives could be very easily and accurately read by this test, but the intermediate zone, which Dr. Eagle characterizes as "doubtful," we were unable to read satisfactorily. Accurate readings of low positives were certainly no easier for us than in the case of a one-plus or two-plus Kahn test. We found in the case of strongly positive sera that this test checked very closely with the other serologic tests. Cases showing a negative Wassermann test and two-plus or three-plus Kahn and Kline were rarely positive by the Eagle Flocculation method. The method is more time-consuming than either the Kahn or Kline method for precipitin tests. Therefore, with the exception of this brief survey, no further work was done with this test.

We acknowledge with gratitude the cooperation of the clinicians of the Indianapolis City Hospital Skin Clinic and the Medical Staff of Fort Benjamin Harrison.

AN EASILY ASSEMBLED, SELF-RECORDING PERFUSION APPARATUS*

TRACY J. PUTNAM, M.D., BOSTON, MASS.

THIS apparatus was devised for the study of the volume of blood flow through the cat's carotid at fixed pressures over long periods of time, but may prove useful for other types of perfusion.

The fundamental mechanism employed is the "Autopulse" (Fig. 1), a device used to pump fuel from the tank to the carburetor of internal combustion engines. It may be obtained at a reasonable price through dealers in electrical automobile equipment. The device consists of a small metal bellows pump of about 0.8 c.c. capacity intake and outlet valves. The bellows is filled by the action of an electromagnet, which pulls against a spring. The spring expels the contents of the bellows at a constant pressure, and at the end of the stroke, contact is closed, which actuates the electromagnet once more. Current is supplied by a storage battery.

To adapt the "Autopulse" to physiologic purposes, it is necessary in the first place to introduce a means of adjusting the pressure. This is done by placing a thin nut between the spring and the arm which supports it and threading a machine screw into it. The end of the screw projects through a hole drilled in the bottom of the sheet metal casing. By turning the screw, the pressure may be adjusted from about 80 to about 250 mm. of mercury.

Next it is essential to arrange an electrical signal to register each stroke of the pump. This is done by soldering the tips of a separate pair of wires in shunt with the electromagnet. The wires run to a signal magnet on the special kymograph to be described below.

Finally, a constant supply of blood from a heparinized animal must be provided. This is derived in the present instance from cannulas in both fem-

Received for publication, December 14, 1932.

oral arteries. To insure that the amount necessary for each stroke is always available and that no more than essential is abstracted from the circulation, a float valve is required. The float chamber consists of a glass tube about 2.5 cm. in diameter, closed at one end by a two hole stopper. A short piece

Fig. 1.—“Autopulse” provided with glass float chamber and float (above). To the right, leading to the float chamber, is the rubber tube and check valve. The outlet, connected to the carotid, is on the further side. The black wires lead to the signal magnet, the white wires to the battery. Notice that both are attached to the same terminal at the base of the solenoid, but that they are attached to opposite sides of the contact points above.

of copper tubing occupies one hole, and is soldered into the intake valve chamber of the pump (after the gasoline filter has been removed, and its projecting support sawed off level). An L-tube leads into the other hole, carrying at its further extremity an improvised cut-off valve. As is illustrated in Fig. 2, this

consists of a length of thinnest rubber tubing, 3 mm. in diameter, which runs between two wire rings fixed permanently in line. On a straight stub of wire at right angles to the axis of the tube, a wire crank is pivoted in such a way that its short arm compresses the rubber tubing when its long arm is elevated. The long arm is actuated by a J-shaped wire, which hooks over the side of the float chamber and rests upon the float. The float consists of a paraffined wood or pasteboard box (a small shaving-soap box would do) 5 to 10 cm. long, fitting easily in the float chamber. When it rises on the column of blood in the chamber, the flow from the femoral is cut off.

It is difficult to guard against the entrance of bubbles of air into the pump. To prevent embolism, the blood is passed from the outlet of the pump into a small inverted bottle, of about 20 c.c. capacity, and out again to the carotid cannula. If any air collects at the top of the bottle, it may be removed by a lumbar puncture needle inserted through the cork. A thermometer also lies in this chamber.

In some experiments the blood was warmed by passing through a coil of fine brass tubing in a thermostated jar; but a much simpler means of heating the air trap, such as an electric bulb placed near it, will suffice for most purposes.

Fig. 2.—Diagram of the shut-off valve attached to the float.

The systolic and diastolic pressures at which the blood is delivered are read off on a mercury manometer, connected to the outlet by a T-tube. The carotid pressure and temperature are not registered directly, as they should be constant, but are written into the record from time to time during the experiment.

The output of the pump varies slightly with different pressures and should be measured directly under the particular conditions which exist for each series of experiments.

Before this perfusion pump had been a week in use, it became obvious that some special means of recording would have to be developed. The paper on an ordinary long kymograph was used up before a base line was established, unless it was run so slowly that individual strokes of the pump were difficult to distinguish, and the ordinary ribbon recorders are not adapted to register alterations in blood pressure. The following apparatus was therefore devised (Fig. 3) using inexpensive ready-made materials whenever possible.

The whole kymograph is mounted on a board 10 inches wide and 30 inches long. Rolls of adding machine paper, three and a half inches wide,

are used to take the record. The paper is suspended on a roller at one end of the board and passes at once under a bridge which carries two of the signal-magnets. It then runs far enough to allow the inked record to dry, before reaching the propelling mechanism.

The kymograph mechanism itself is built mostly from the gear box of an "Erector" set, obtainable at any toy shop. The paper is pulled by three wheels each composed of two of the discs intended to form the wheels of the toy automobile which can be built from the set. Slipping is prevented by flat "tires" of appropriate-sized rubber bands cemented to the circumference. The strip of paper slides upon a piece of celluloid which is bent around the front of the wheels so that the paper is in elastic contact with a full quadrant of their surface.

Fig. 3.—The kymograph assembled. At the left are the propelling wheels. Notice that the paper is curved around them. Above are the gear box and motor with rheostat. The connection between the mercury manometer and syringe used as recorder is shown. At the right is the transformer and electric clock.

The wheels are fixed between bearings to a length of shaft which extends into the gear box of the "Erector" set. The gear box affords a quadruple reduction of speed including a worm gear, but this is not enough for the purpose. In the present set the motor of an automobile windshield wiper has been used which contains an additional triple reduction within itself, and is operated by a transformer. A small motor with a worm gear reduction incorporated in it, such as may be obtained from laboratory supply dealers, would be preferable. Some sort of rheostat speed control is essential.

The transformer in the present set is also used to operate the signal magnets. There are three of these: one in shunt with the "Autopulse" pump, one to mark time, and one to record the application of stimuli, administra-

tion of drugs and the like. They are made from ordinary electric bells (of the best grade) with the bell, knob, cover and stamped base removed. For writing points, the smallest sized Keuffel and Esser lettering pen tips are used. The shank is bent into a sleeve to fit the vibrator of the bell. These writing points should be washed after use and kept in alcohol to prevent corrosion. If it were desired to eliminate the transformer, the signals could be operated from the storage battery with appropriate resistance interposed.

The timer is made of an electric clock with a sweep second hand. The best method of converting it to scientific purposes varies with the model of clock, but platinum contact points should be used in any case. In the present device an interval of fifteen seconds is convenient.

Blood pressure is recorded continuously from a mercury manometer connected by a T-tube to the intake of the pump and the femoral arteries. A thick-walled rubber tube passes from the distal end of the mercury manome-

Fig. 4.—Sample of record. Perfusion of cat's common carotid under amytal. Effect of injection of 1/10,000 adrenalin into carotid: increase of blood pressure, slowing of strokes of pump.

ter to the tip of a 5 c.c. syringe. The space between the top of the mercury column and the piston of the syringe is filled with 50 per cent glycerine, and the plunger of the syringe is oiled. Any movement of the column of mercury is transmitted to the piston of the syringe but the resulting excursion is inversely proportional to the squares of the radii of the two tubes respectively. The syringe is fastened horizontally at the edge of the strip of paper and a writing point secured to the piston. It is possible to obtain tracings of individual pulse beats by this arrangement, although of course on a reduced scale.

The advantages of this kymograph are that it is inexpensive, portable, and compact. The timing device is self-contained. Records may be taken continuously over several hours and will show several signals simultaneously as well as recording blood pressure. Annotations may be made directly on the paper at the time they occur obviating the inconvenience of a separate set of notes.

A PIPETTE WASHING DEVICE*

THOMAS P. NASH, JR., PH.D., AND WILLIAM KRAUSS, M.D., MEMPHIS, TENN.

THE washing of the numerous pipettes required in the routine and research work of biologic laboratories is a vexatious and time-consuming detail. For a number of years we have employed for this purpose, and with much satisfaction, the device illustrated in Fig. 1.

The essential feature of the apparatus is the brass nipples threaded into lines of $\frac{3}{8}$ -inch or $\frac{1}{2}$ -inch brass pipe. Brass rod of $\frac{1}{4}$ -inch diameter is cut

Fig. 1.

into $\frac{3}{4}$ -inch lengths. These are threaded at one end and drilled from the opposite end with a $\frac{1}{8}$ -inch drill, the final 2 or 3 mm. at the threaded end being drilled through with a $\frac{1}{32}$ -inch drill. When these nipples are screwed into water lines the small diameter of the bottom openings suffices to maintain sufficient pressure in the system to force water through the tallest pipette even though only one pipette may be in the apparatus. The nipples are fitted with short lengths of rubber tubing which receive the tips of the inserted pipettes. In Fig. 1 only two of the nipples are shown with rubber connections

*From the Departments of Chemistry and Medicine, College of Medicine, University of Tennessee.

Received for publication, December 2, 1932.

and holding pipettes. Some suitable support, such as that illustrated, must be provided for the upper portion of the pipette. Only a moment's time is required to insert a pipette, and washing with constantly changing water then continues automatically until the pipette is removed.

The apparatus pictured is designed to be connected by rubber hose to a water cock, and may be moved from one sink to another. In our laboratories we have found it convenient to have a single line of nipples permanently installed near the bottom and at one end of each sink where the device interferes least with other uses of the sink.

A surprisingly large number of nipples may be assembled in a single unit without loss of efficiency. Since, however, water escapes from every outlet whether or not these are occupied by pipettes, a larger capacity unit than normally sufficient leads to an unnecessary wastage of water.

Test tubes, centrifuge tubes, and other similar pieces are conveniently and automatically washed in this apparatus by inverting them over glass tubes connected to the nipples.

THE CALIBRATION OF WHITE BLOOD CELL DILUTION PIPETTES*

F. LOWELL DUNN, S.B., M.A., M.D., OMAHA, NEB.

THE technical skill required in the manufacture of blood cell dilution pipettes must excite the admiration of all who give thought to the problem. Obviously such micro pipettes must show variations in precision. This fact is recognized by the manufacturers, some of whom provide factory certificates and guarantees of accuracy or individual certification either by themselves or by the Bureau of Standards. Textbooks of clinical pathology show a widely varied response to the possibility of pipette errors. At the one extreme is the statement that only pipettes certified by the Bureau of Standards should be used in clinical laboratories, while at the other extreme is the complete omission of any comment regarding the possibility of such errors. Probably the majority of physicians assume dilution pipettes as purchased to be sufficiently accurate for clinical purposes, or check them against other pipettes to maintain uniformity. Using the same pipette for consecutive blood counts on the same patient is a common device for ascertaining relative changes in leucocyte counts. This is a tacit admission of error in apparatus and is at best an inconvenient method in laboratories where a large number of pipettes are in daily use.

The extra charge made for reliable certification seems most reasonable to anyone who has undertaken such calibration. There is, however, a general impression among clinicians and hospital administrators that such certification is warranted only for purposes of academic research.

*From the Department of Clinical Research, University of Nebraska College of Medicine.
Received for publication, December 23, 1932.

The Bureau of Standards specifications for dilution pipettes with a 1 to 10 ratio require (in addition to certain details of construction) that the dilution must not be in error by more than ± 3.5 per cent. This is, of course, the pipette error alone and does not include other possible sources of error such as, (1) technical manipulation of pipette and hemocytometer, (2) physiologic variations, and (3) errors in the construction of the hemocytometer. Since rises in leucocyte counts of 1000 to 2000 per cubic millimeter are often determining factors in formulating opinions regarding treatment, a method error of 10 per cent looms large and an error of ± 3.5 per cent in the pipette alone is a large fraction of this total error.

The accidental discovery of a defective pipette in our own service raised the question of the accuracy of dilution pipettes in current clinical use. New lots of pipettes were supposed to be checked against older lots for consistency but this had been neglected because of lack of time. We were unable to obtain any impartial information and the discrepancy in textbooks of clinical pathology made it desirable to determine whether the extra cost of calibration was a justifiable expenditure. Through the courtesy of several physicians we obtained for calibration 86 white cell dilution pipettes.

METHODS

After inspection the pipettes were rinsed with nitric acid, bichromate cleaning mixture, water, alcohol, and ether until examination showed them to be clean.

Gravimetric.—The weights of distilled water or 1 per cent fuchsin included between the tip and the "0.5" mark, and between the tip and the "11" mark were determined. The necessary precautions in calibration of volumetric ware were observed.

This method was slow and since the weight of water included between the tip and the "0.5" mark was often not over 10 mg. it was necessary that the manipulations required in filling the pipette and the weighing itself must not introduce errors of over 0.1 mg. to determine the pipette error within 1 per cent. The necessity for technical skill and experience was shown by the amount of practice required before consistent results could be obtained, probably making this method available only to those who had survived the equivalent of an elementary course in quantitative analysis.

Peffer Method.—A much more promising method was that of E. L. Peffer of the Bureau of Standards.¹ His excellent instrument eliminates the handling of the pipettes during the calibration, requires considerably less skill, and is five to ten times faster than the gravimetric method. To construct a duplicate of his fine instrument was prohibitive, but it was obvious from his description that the basic features could be satisfied at a negligible cost.

The device, as assembled by us, is illustrated in Fig. 1 with the protective cotton cover removed. It consists of a small reservoir containing 1 per cent fuchsin, a one hole rubber stopper to fit the bulb end of the pipette, and a piston by which the fuchsin can be forced up into the pipette, the volume of liquid being measured by a micrometer screw feed on the piston. The pipette is placed vertically in the stopper, with the tip up. The solution is forced to the "11" mark and a reading is taken. It is then forced up to the "0.5" mark and to the tip, readings being made at each level. The result is a measurement of the desired volumes of the pipette in terms of micrometer screw piston displacements from which the dilution value of the pipette can be quickly calculated. The small reservoir in our apparatus was a Pyrex tee. A Brown and Sharpe micrometer head was cemented into one end of the tee with De Khotinsky cement. The other end was closed with cement. The tee was used in order to secure rigid clamping to the ring stand by the usual laboratory supports. The upright portion of the tee was fitted with a rubber stopper. A single hole was bored,

the size being selected to fit tightly the bulb ends of the pipettes to be calibrated. The inner end of the rubber stopper was made concave so that air bubbles would not be trapped, but could be forced out through the hole in the stopper. The system was then filled with 1 per cent fuchsin and all air bubbles carefully expelled.

Slight fluctuations of temperature of the fuchsin solution produce marked variations in the height of the solution in the capillary tube of the pipette. Consequently the apparatus must be carefully shielded. Peffer shielded his apparatus by a vacuum container. We wrapped the tee with several layers of cloth before clamping it to the ring stand, and then surrounded tee, clamps, and part of the ring stand with cotton, leaving only the rubber cork and the micrometer head exposed. The cotton was put on in layers to a thickness of two to four inches, being careful that all air channels were closed. The knurled portion of the micrometer head was covered with several wrappings of cloth to protect it from the heat of the hand. This protection was sufficient if drafts were avoided, although on a few days

Fig. 1.—Dilution pipette calibrator for white blood cell pipettes utilizing some of the features of Peffer's instrument. A, white pipette; B, micrometer head; C, tee reservoir. The cotton cover to minimize thermal effects has been removed.

temperature fluctuations made consistent readings impossible. Later, by partly filling the tee with hard paraffin, the volume of liquid was reduced from about 30 c.c. to 8 c.c. and the temperature effect was definitely less marked.

Several practical details developed during use. The rubber stopper should fit the tee and the pipette tightly and without any tendency to crawl. It was preferable to cement the stopper to the tee. Any crawl was apparent in duplicate readings, or the shift in the fluid level could be observed after waiting a minute or two. The crawl could be accelerated by gently tapping the pipette with a pencil. After setting the level at the "11" mark, it proved useful to tap the pipette to minimize any crawl during the subsequent readings. Bubbles occasionally adhered to the glass bead in the bulb of the pipette. These should be watched for very carefully during the filling of the bulb and should be removed by tapping.

Any air in the system caused erratic results and lag in response when the piston was moved. This was due to incomplete filling of the reservoir or to failure in keeping the

hole in the stopper sufficiently filled with fuchsin. The reservoir was kept filled by dropping the fuchsin solution on the stopper and drawing it in by means of the micrometer screw. The pipettes must of course be dry for each set of measurements, although measurements of the interval between the tip and the "0.5" mark could be duplicated usually without drying between determinations.

The meniscus should be set flat across the orifice when the setting at the tip is made. Many pipettes show a constriction in bore at the tip, and it is our experience that lag due to small amounts of air show up most conspicuously in this region. The setting at the tip is best made with the aid of a magnifying glass.

The method described above proved much more satisfactory than the gravimetric. If the reservoir is so designed that air bubbles are not trapped, the system is easily filled. Skill in attaching the pipettes is quickly acquired, and it is easy to control accurately the level of the solution by the micrometer screw. This method measures the pipette error directly and does not include the errors of filling and handling the pipette as in the gravimetric method.

Colorimetric Method.—The dilution value of the pipette can be measured directly in a colorimeter against a standard dilution. Several colored solutions were tried and 20 to 30 per cent chromic sulphate was selected because of the high sensitivity of the eye for green and because twenty-two fold dilution still gave a satisfactory intensity in the colorimeter at a cell depth of 20 mm. The standard dilution was a 1:22 dilution of the strong solution. The concentrated chromic sulphate solution was sucked up to the "0.5" mark and then diluted to the "11" mark with distilled water. After shaking a moment the entire contents were discharged into a colorimeter cup. This process was repeated, drying the pipette each filling until sufficient solution was obtained to give an effective depth of 20 mm. With microcolorimeter cups one to three fillings were sufficient, the larger all-glass cups requiring four or more fillings. This might appear to be a drawback in the method, but it is compensated by the fact that the colorimeter reading is an average of several fillings.

The evaporation of the liquid in a glass microcolorimeter cup was measured and found to be about one milligram in fifteen minutes at 27° C. on a dry day when the cup was covered with a watch glass. Since the total volume of leucocyte pipettes is usually 0.25 c.c. or more, this loss is not significant. Furthermore with a suitable suction pump and the use of alcohol and ether the pipettes can be cleaned and dried in a minute or two so that three fillings and the necessary cleanings can be accomplished within ten minutes. A 30 per cent chromic sulphate solution was tested for change of color over the temperature range of 24 to 45° C. None was observed.

The green color can be very satisfactorily matched in the colorimeter, but faulty use of such instruments is so common that several details should be mentioned. The zero settings should be carefully checked. The colorimeter should be symmetrically placed with respect to the illumination. Any inequality in the fields should be located and rectified and not compensated by twisting the position of the instrument with respect to the light. If the plungers are not dry, they can be rinsed with the standard solution since it closely approximates the strength of the unknown. When a series of pipettes are to be calibrated, the standard solution should be changed frequently enough to avoid appreciable evaporation. The colorimeter light should be turned off when readings are not being made.

This colorimetric method appeared to us logical and was much easier to do than the difficult gravimetric method. Colorimetric methods are more familiar to the clinical laboratory worker than gravimetric. The hydrometric method of Peffer is perhaps not so applicable to general use because of this drawback of unfamiliarity. The colorimeter method showed no greater variation in our hands than those obtained with the use of our makeshift micrometer screw calibrator. With the increase in ruggedness and precision of photoelectric circuits the adaptation of the colorimetric method to a photoelectric one is an obvious technical procedure. Since the colorimetric readings for certifiable pipettes are within ± 3.5 per cent, it might

prove unnecessary to use a photometric head, the readings being made by galvanometer deflection. The speed of such a device should materially reduce the cost of pipette calibration.

The calibration of the various pipettes was controlled by: (1) repeated checks on different days, (2) check against the gravimetric method, and (3) comparison with the Bureau of Standards certified pipettes. Three or more readings were averaged. Most of the readings were made with the micrometer screw calibrator.

DISCUSSION

A few of the pipettes were discarded because of tips broken sufficiently to affect the accuracy, leaving a total of 84 to be discussed. Of these 10 bore no visible identification mark while the rest included 13 different distributors' names or identification marks. All but 18 had a serial number. We do not know how many manufacturers were represented in this series of 84 pipettes, but we are informed that the manufacture of these pipettes is a highly specialized industry and confined to very few firms. Only one pipette

Fig. 2.—Frequency curve of errors of 84 white blood cell dilution pipettes.

had been recognized as being in error prior to our calibrations. One pipette, not included in the series, had no mark whatever on the capillary stem. We were unable to associate defective pipettes with any particular identification mark. It was possible to obtain catalogue specifications, guarantee, or factory certificates on 63 pipettes. The small size of our series does not permit in any sense a general statement but with this qualification the nature of the guarantee or specification had little or no bearing on the accuracy of the pipette except in those cases where there was an explicit statement that the pipette had been individually calibrated. All pipettes that had been individually calibrated were within the tolerance stated. Under present conditions the inference can be tentatively made that individual calibration is necessary to eliminate defective pipettes.

The results of our calibrations were plotted in a frequency curve to conserve space (Fig. 2). Of the 84 tested, 24 (28 per cent) showed errors in excess of ± 3.5 per cent. Of these, 10 (11.5 per cent) were in the group 3.5 to 5 per cent, 12 (14 per cent) in the group of 5 to 10 per cent, and 2 were over

10 per cent, one of which had an error of 38 per cent. It is interesting that plus errors were more common than minus errors and in the ratio of 68 to 16. Since a portion of the calibrations were done both by the micrometer screw piston method and by the colorimetric method we were unable to explain the frequency of the positive errors on the basis of the method of calibration.

With 28 per cent of the pipettes showing errors in excess of ± 3.5 per cent, the possibility of serious errors arising in laboratories where a large number of pipettes are in use is far from negligible even for clinical purposes.

SUMMARY

1. Calibration of 84 white blood cell dilution pipettes in clinical use showed 28 per cent to have errors in excess of ± 3.5 per cent, 11.5 per cent to have errors of 3.5 to 5 per cent, and 14 per cent to have errors of 5 to 10 per cent with two having errors of 11 per cent and 38 per cent respectively.

2. Positive errors were more common than negative in the ratio of 68 to 16.

3. A colorimetric method for the calibration of dilution pipettes has been described.

DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

PERTUSSIS, Production of Antipertussis Serum of High Titer, Bailey, J. H. *J. Infect. Dis.* 52: 97, 1933.

By repeated intraperitoneal injections into cocks of massive doses of a suspension of live, virulent pertussis bacilli, an antipertussis serum of high titer, not causing serum sickness even in large doses, was produced, which, in the limited trial afforded it, gave evidence of being of value in the treatment of pertussis in children. No definite statement as to the therapeutic value of this serum may be made until a greater number of patients have been treated.

SYPHILIS, Serodiagnosis of, Denison, G. A., and McDonald, E. G. *Am. J. Syph.* 17: 90, 1933.

Serologic tests for syphilis because of their complicated and empiric nature are subject to variation, and the use of standardized technics in different laboratories does not mean that comparable results will be obtained. Each clinician should have a very definite idea of the clinical level of the tests performed for him. Clinician and serologist should work together, each sympathetic of the other's problems.

Various tables are compiled showing comparative results obtained with several methods as used in a board of health laboratory. However, it should be emphasized that similar results would not necessarily follow in other laboratories using the same methods. For this reason only very generalized deductions should be made.

A close comparison of methods cannot be made by tabulating results on all specimens from cases of a general nature since the large number of negative routine examinations minimize the differences. True comparisons are best made on treated and untreated syphilitic cases. Finally, where results disagree a close check of clinical findings should be made to determine the correlation. Judged in this way the apparent working agreement of 93.6 per cent obtained on all specimens with four antigenic tests is reduced to 89.1 per cent in untreated and 79.5 per cent in treated syphilis. The greatest number of disagreements occur in recently treated cases. However, there are always a small number of syphilitic cases which for some reason are positive only with one method or another.

The authors' experience justifies the conclusion that no single test is ideal for confirmatory diagnosis and treatment of syphilis, that none of the technics studied have any inherent specific qualities, and that the best results may be expected from the use of multiple tests which include at least one precipitation and one complement fixation method. The authors believe that multiple tests allow greater latitude in the quantitative estimate of the patient's serology, and, thereby, serve as a better guide for treatment.

PNEUMONIA, Specific Serum Treatment of Type I, Parsons, J. W., and Sutcliff, W. D. *Am. J. M. Sc.* 186: 52, 1933.

The effectiveness of two methods of dosage of specific serum in the therapy of pneumococcal Type I lobar pneumonia is compared in two groups of 12 cases each, treated before the fifth day of their disease. In the first group amounts of serum were given (15 to 105 c.c., average 45 c.c.), just sufficient to maintain agglutinins in the circulating blood, as determined by a rapid bedside method. In the second group a larger, empirically selected dose (75 c.c. or more, average 79 c.c.) was given to each patient.

In both groups the response to the therapy was satisfactory as shown by the short duration of the disease after therapy, and by the death rate. On the average, the course of the disease in the 12 empirically treated patients was much shorter than the average course of a larger series of cases treated in the same manner, but this unusual result in a small series of cases does not necessarily indicate the superiority of this method of therapy.

Evidence is given to indicate that the persistence of agglutinins for the hemologous organism is an index that a sufficient amount of antipneumococcic serum has been administered to produce a satisfactory therapeutic result.

TUBERCULOSIS: The Question of Tubercle Bacilli in the Blood in Advanced Pulmonary Tuberculosis, Corper, H. J., and Damerow, A. P. *Ann. Rev. Tub.* 28: 118, 1933.

Tubercle bacilli were not found to be present in the blood of 120 patients with advanced pulmonary and generalized tuberculosis at the National Jewish Hospital and Fitzsimons General Hospital at Denver, Colorado, in spite of the fact that each blood specimen was submitted to four different methods of examination for tubercle bacilli, namely, guinea pig inoculation, and three different culture methods. While control tests proved the efficacy of the culture methods used for discerning small numbers of tubercle bacilli in human and animal blood, acetic acid, as recommended by Loewenstein, destroyed small numbers of human tubercle bacilli, while saprophytic acid-fast bacilli would survive such treatment, thus vitiating the results obtained with this reagent.

In addition to the 120 cases studied, over 200 routine smaller specimens of blood obtained from patients in a tuberculosis sanatorium and examined by means of two reliable culture methods, the tissue-substrate method and the sulphuric acid crystal violet potato cylinder method, did not reveal a single positive culture for tubercle bacilli among these specimens. As a result of the examination of the blood from the 120 cases of advanced tuberculosis two specimens yielded saprophytic acid-fast bacilli, which could readily be differentiated from pathogenic tubercle bacilli by animal inoculation and reliable culture methods.

Tubercle bacilli were found to grow well when present in small numbers on a sulphuric acid treated and sodium bicarbonate or sodium hydroxide neutralized blood residue or on inspissated defibrinated blood, making it appear that the acid- or heat-treated or sterilized blood pigments are not detrimental to the growth of tubercle bacilli. The macroscopic type of culture obtained on the blood medium differs from that seen on potato or on egg, which also differ from each other.

The Congo red potato flour egg medium (Loewenstein) is a good one for human and bovine tubercle bacilli, but it is no better than a simple potato cylinder or inspissated egg yolk medium, and it possesses the disadvantage of being unnecessarily encumbered with expensive and unessential ingredients.

It appears that human or bovine tuberculo bacteremias, in the sense that tubercle bacilli circulate in the blood for a fairly long time or that the bacilli multiply in the blood, are not borne out by these studies, although it is not intended to convey the impression that occasional embolic disseminations (showers) from disintegrating tuberculous foci do not occur or that there may not exist terminal periods in the course of the disease when numerous showers of caseous products containing viable bacilli may make it possible to find them in the blood of man and experimental animals. However, such a condition of tubercle bacilli in the blood is far from being the common event, according to the observations made in this study.

It would appear also that embolic showers (embolemia), when they do occur in man, are rapidly removed from the circulation in the usual case of tuberculosis.

DIPHTHERIA: Active Immunization Against, by a Single Injection, Strauss, H. W. *J. A. M. A.* 101: 192, 1933.

A concentrated diphtheria toxoid incorporated in hydrous wool fat has been injected intramuscularly and actively immunized 99 per cent of 103 patients within a period of two

months. In the majority of cases, immunity developed in from three to four weeks and, in one case, as early as two weeks.

Because of the early development of active immunity, a preparation such as that described may have a practical usefulness in checking an epidemic of the disease. A single injection method has obvious practical advantages.

The material used in this study was prepared in the following manner: Diphtheria toxoid (M.L.D. 500 per c.c.; L. 0.13; L.F. 0.1), 7,300 c.c. was placed in cellophane bags and fanned at room temperature until the volume was reduced to 250 c.c. The dark colored granular precipitate that formed was removed by centrifugation. The supernatant fluid was diluted up to 730 c.c. in the process of twenty-four-hour dialysis in a cellophane sack and by the addition of distilled water. Phenol (0.5 per cent) was added and the solution was filtered through a Berkefeld candle. The least fatal dose of the concentrated solution was 0.014.

In a similar way, the solution was further concentrated to 73 c.c. (100:1 concentration). This was preserved, after Berkefeld filtration, with merthiolate in a final concentration of 1:10,000. This concentrated fluid was found to contain 300 flocculating units per cubic centimeter.

Two batches of the lanolin mixture were prepared as follows: Batch 301-H-11 was made by thoroughly mixing, at 42 C., 100 c.c. of sterile hydrous wool fat and 50 c.c. of concentrated diphtheria toxoid. One cubic centimeter of this mixture thus contained 100 flocculating units and 0.2 c.c. contained 20 flocculating units. Batch 301-H-12 was made in the same way as 301-H-11 with the exception that, to each quantity of 0.2 c.c. of the mixture, 0.05 c.c. of sterile olive oil was added.

The material was received in individual miniature antitoxin syringes, each containing a single dose. The preparation is of the consistency of a soft wax and is easily expelled from the syringe.

No reactions were observed in children under five years of age. In the school age group there was an occasional complaint of soreness in the arm for a day or two with slight local redness and in one case a temperature of 101 during the first twenty-four hours. In the adult group, five who had positive Schick but negative control reactions were included in the series. They complained only of a heavy feeling in the arm. Five other adults (not included in the series) who gave positive Schick and control tests were given the injection. Of these, two gave severe reactions with a rise of temperature to 102, headache, malaise, a large area of local redness with induration, and regional adenitis. The fever subsided in twenty-four hours. The three remaining persons had mild local reactions without constitutional symptoms. The reactions to be expected, then, are the same as those obtained with ordinary toxoid. They are infrequent and quite mild in older children and absent in those of preschool age. The more severe reactions are to be expected in those patients who give positive reactions to both Schick and heated control material.

PERTUSSIS: Occurrence of the Bordet-Gengou Bacillus, Kristensen, B. J. A. M. A. 101: 204, 1933.

The results of this study are conformable with the hypothesis that the Bordet-Gengou bacillus is the etiologic agent of whooping cough.

The cough-plate method has been used for sixteen years at the State Serum Institute in Copenhagen and has proved to be of practical value. It is the best method for diagnosing the disease early.

An isolation period of four weeks after the onset of the typical paroxysm has in practice been sufficient for school children.

Healthy carriers have not been found outside of families in which whooping cough exists.

Abortive and quite atypical cases of whooping cough are frequently found, and the author believes they play an important rôle in the spread of the disease.

PUERPERAL INFECTION: Relationship Between Exogenous Throat Streptococci and Kellogg, F. S., and Hertig, A. T. *Trans. Am. Assn. Obst. Gynec. & Abd. Surg.* 87: 1932.

From a study of an epidemic in the maternity wing of a well-equipped general hospital in 1931, it is concluded:

That nasopharyngeal carriers of hemolytic streptococci (and perhaps other organisms) are a most dangerous source of frequently fatal sepsis to women in childbirth from the moment labor begins (and possibly before), to the end of the puerperium (at present an unassignable date but at least fourteen days after delivery).

That "silent carriers" are potentially as dangerous as persons acutely sick with temperatures, save for less likelihood of coughing or sneezing, although, usually, a history of some acute exacerbation in the not distant past may be obtained from the carrier.

That perineal contacts are presumably the most frequent method of transmission; either by coughing, sneezing or talking with the patient during perineal precautions or by incomplete manual asepsis after self-infection of the hands by the carrier, as by the use of a handkerchief; but that for the present other less direct methods must be assumed, and guarded against.

Hence, that every carrier is a source of danger and must be eliminated or be masked adequately at all stages of labor and the puerperium and be absolutely trained and trustworthy about digital asepsis.

That since pupil nurses are untrained and unhabited to conscientious digital asepsis, it is a wise precaution to culture each one on entrance to a maternity hospital and to eliminate each one temporarily until the throat is negative for hemolytic streptococci.

That other personnel, i.e., doctors and graduate nurses trained in asepsis, following rules akin to those given above, will in all probability not prove a hazard to patients.

That the question of ward attendants, especially those serving food, must be carefully considered.

That a single case of puerperal sepsis in an institution calls for immediate rigid investigation and drastic measures based on this to limit spread.

MILK: The Use of Glycerol as a Preservative for Specimens to Be Examined for Hemolytic Streptococci, Gilbert, R., and Clark, M. E. *Am. J. Pub. Health* 23: 720, 1933.

The addition of glycerol to make a 30 per cent concentration has been found to enable recovery of streptococci from milk after seven days at room temperature or after ten days' refrigeration. It is thus of value in the study of epidemics of septic sore throat.

THYROID DISEASE: Effect of Treatment on Blood Cholesterol in, Hurxthal, L. M. *Arch. Int. Med.* 521: 86, 1933.

The blood cholesterol is low in toxic thyroid states, and is brought to a normal level partly by preoperative treatment but chiefly by subtotal thyroidectomy.

The reciprocal relationship between the average elevation of the basal metabolic rate and the average lowering of the blood cholesterol level in toxic goiter, is further confirmed by the results of treatment presented in this paper.

There appears to be little difference between the change in the blood cholesterol values in exophthalmic goiter and that in toxic adenomatous goiter as the result of treatment.

The blood cholesterol in nontoxic adenoma or adenomatous goiter undergoes little or no change as the result of removal of the growth.

The blood cholesterol determination is of distinct but limited value in the diagnosis of hyperthyroidism.

BLOOD CULTURES: Comparative Study of, Taken With Kendall and Routine Mediums. Friedberg, C. K. Arch. Int. Med. 52: 120, 1933.

One hundred and three routine blood cultures were made for 77 patients suffering from a variety of febrile illnesses suggesting the presence of bacteremia. Simultaneously, flasks containing K medium were inoculated with blood from these patients.

The K medium showed 4 per cent less positive results than the ordinary routine method. Compared with the individual flasks and plates used in the ordinary method, the flask of K medium showed slight inferiority to some and slight superiority to other individual units.

Other disadvantages were found in the difficulty and expense of preparing the medium and the greater time necessary before an organism could be identified.

Repeated subcultures from the original K flask failed to show any invisible, filterable forms which could be converted to the ordinary state by transfer to solid medium as alleged by Kendall. There was no evidence in the cases studied to show that the clinical picture was due to a filtrable, invisible form of an organism which did not show itself on the ordinary mediums.

In several instances common organisms were found to pass through the Berkefeld filter, suggesting the possibility that the K medium may have had some influence in impairing the efficiency of the filter.

LIVER FUNCTION: An Appraisal of the Modified Dextrose Tolerance Tests, Ricketts, H. J. Arch. Int. Med. 52: 147, 1933.

The test in question follows:

1. Estimation of blood sugar during fasting was made in the morning.
2. The patient was then given 20 units of insulin.
3. Twenty minutes later, the patient was given 50 gm. of dextrose in 500 c.c. of water by mouth, followed by 1,000 c.c. of water by mouth.
4. Blood sugar determinations were made at one-half hour, one hour, two hours and three hours after the ingestion of the dextrose and water.

The modified dextrose tolerance test of the function of the liver, as described by Althausen, Gunther, Lagen and Kerr, was performed on ten patients who were considered to have normal livers at the time of examination, and on four patients with frank hepatic disease.

Of the ten normal patients, nine responded to the test by a drop in blood sugar to points considerably below the critical level for normal reactions, and showed symptoms and signs of hypoglycemia.

Of the four patients with frank hepatic disease, three responded by definite chemical and clinical hypoglycemia.

There was no essential difference between the behavior of the normal and the abnormal groups.

The modified dextrose tolerance test in its present form is not a satisfactory measure of the metabolic function of the liver.

PREGNANCY, Hormone Diagnosis of Viability of, Spielman, F., Goldberger, M. A., and Frank, R. T. J. A. M. A. 101: 266, 1933.

Thirty-three pregnancy cases in which missed abortion was suspected or expected were studied from the hormonal aspect in order to determine the relationship between the female sex hormone of the blood and the pituitary hormone of the urine on the one hand, and fetal life or death on the other.

The Frank-Goldberger method was used in the blood studies, and either the Aschheim-Zondek or the Friedman test in the urine studies.

A negative female sex hormone reaction was obtained when the fetus was dead (23 cases) and a positive reaction when the fetus was alive (8 cases). The results here were 100 per cent correct.

A negative pregnancy reaction was obtained when the fetus was dead in eleven cases, and ten cases gave positive reactions in spite of dead fetuses (approximately 50 per cent correct).

The female sex hormone blood determination has proved itself in this small series an absolute indicator of whether a fetus is alive or dead. The urine pregnancy test is of value only when the reaction is negative.

The presence or absence of the hormones depends on the degree of involution of the placenta and its attachment to the uterine wall.

TUBERCULOSIS: The Tuberculin Patch Test, Grozin, M. Am. J. Dis. Child. 46: 17, 1933.

The tuberculin patch test is made by moistening a piece of adhesive plaster with 1 or 2 drops of tuberculin and applying it to the skin, which has previously been cleaned with ether. For control, a piece of adhesive plaster without tuberculin may be used. A positive reaction is indicated by redness studded with papules and vesicles.

A study of 176 cases showed that this method compared favorably with the Pirquet test as to reliability.

Its advantages over the Pirquet test and other tuberculin tests are:

- a. It is absolutely painless and therefore does not spoil the relation between child and physician, or frighten a neurotic patient or anxious mother.
- b. It requires no boring, puncturing, scratching or rubbing.
- c. It requires no sterilization of instruments, such as lancets, needles, and syringes.
- d. There is no danger of infection.
- e. It is of much simpler technic, so that it can be done by nurses without much training.

f. It is less time-consuming, since there is no waiting for the tuberculin to dry or to act on the skin, or watching that the child does not wipe it off or spread it to the area of control. It is therefore of advantage when large numbers are to be tested or in busy practice.

g. It is possible to control the area of reaction, since this is usually limited to the surface covered by the adhesive plaster. In other percutaneous tests, such as the Moro, the reaction cannot be controlled, once it has started, because the tuberculin must be rubbed into the skin, and friction of clothes tends to spread it still further. In the tuberculin patch test the reaction can be regulated by the size of the adhesive plaster, by the number of drops of tuberculin and by the strength of the dilution.

h. It is easier to interpret the results with the tuberculin patch test, because the area of reaction can be arbitrarily enlarged by applying larger pieces of adhesive plaster, more tuberculin and tuberculin of greater concentration.

PNEUMONIA IN INFANTS, Due to *B. Mucosus-Capsulatus*, Jerguson, J. A., and Tower, A. A. Am. J. Dis. Child. 46: 59, 1933.

Two cases of lobular pneumonia in infancy caused by *Bacillus mucosus-capsulatus* have been reported; the twins were seven months old, a girl and a boy. The girl contracted the disease first and died on the eighth day. The boy became ill two days after the onset of the illness in his sister but completely recovered after thirty-two days' hospitalization.

Bacteriologic examination of the throat and tracheal secretion is the most important procedure from a diagnostic standpoint. The extreme pallor of the skin and dehydration, the cough and mucopurulent nasal discharge in the two cases described in this report, together with the vomiting and diarrhea which cleared up early in the disease, are suggestive from a standpoint of differential diagnosis.

Pneumonia in infants due to *Bacillus mucosus-capsulatus* may not terminate fatally. The pulmonary involvement is, perhaps, most often lobular, and the roentgen signs which are characteristic of the disease in adults may not occur in infants.

HEMOGLOBIN, Content of Blood in Infants, Elvehjem, C. A., Peterson, W. H., and Mendenhall, D. R. *Am. J. Dis. Child.* 46: 105, 1933.

A hemoglobin curve for infants constructed from 2,000 determinations on 750 subjects varying in age from birth to five years is given.

The hemoglobin content of the blood of infants was found to be high (22 gm.) but it fell rapidly and reached a low point at the age of from eight to twelve weeks. There was an increase between the ages of twelve and twenty-four weeks, and a slight decrease thereafter. The hemoglobin remained between 11 and 12 gm. until the infants were about two and one-half years old, after which it increased gradually.

The rapid drop during the first few weeks of life and the low hemoglobin values recorded during the first six months were not prevented to any appreciable extent by the feeding of a good diet of natural foodstuffs. The hemoglobin values of the children on the special diet, however, began to increase at an earlier age than the average values for all the children.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

The Aetiology of Tuberculosis*

THIS is an English translation made by Dr. and Mrs. Max Pinner of Robert Koch's original communication on the etiology of tuberculosis which appeared in the *Berliner Klinische Wochenschrift* the tenth of April, 1882. The present volume was prepared by the National Tuberculosis Association to commemorate the fiftieth anniversary of the discovery of the cause of consumption. Dr. Allen Krause contributes an introductory appreciation of the epoch-making contribution of Koch. The booklet is illustrated with facsimiles of the first page of Koch's original paper and several other pertinent photographs.

Only two English translations have previously appeared, one in the *Canada Medical and Surgical Journal*, 1881, and the other in the *Cincinnati Lancet and Clinic*, 1883.

Koch's original contribution, long since a classic in medicine and an epoch-making paper, should long since have been available in this form and the translators and the Tuberculosis Association are to be congratulated.

Calcium Metabolism and Calcium Therapy†

AN EXHAUSTIVE and at the same time authoritative treatise on our knowledge of the metabolism of calcium and its use in the treatment of disease. While the major portion of the volume is given to those diseases in which there is a clear-cut error in calcium metabolism, the author also includes a discussion of quite a variety of diseases in which the use of calcium is certainly a moot question. The author of course recognizes this fact and outlines the treatment that has been recommended in this particular type of disease by those who claim to have obtained good results.

Outline of the Cranial Nerves‡

THIS is a small reference manual for students and for those of us who after a certain number of years find it difficult to recall the origin, distribution, functions, etc., of the cranial nerves. One of the author's innovations which appears to be especially logical is his process of tracing the sensory nerves from the sensory end organs backward centrally, rather than in the usual reverse. The motor organs he traces from the central point of origin of impulse to the periphery. One who has learned the cranial nerves with this method should be better able to keep them distinct in his mind.

*The Aetiology of Tuberculosis. By Dr. Robert Koch. A translation from the German of the original paper announcing the discovery of the Tubercle Bacillus, read before the Physiological Society in Berlin, March 24, 1882, and published in the *Berliner Klinische Wochenschrift*, 1882, xix, 221, specially prepared for The American Review of Tuberculosis, March, 1932, by Dr. and Mrs. Max Pinner. With an introduction by Dr. Allen K. Krause. Cloth, pages 48. Published by the National Tuberculosis Association, New York, 1932.

†Calcium Metabolism and Calcium Therapy. By Abraham Cantarow, M.D. Instructor in Medicine, Jefferson Medical College; in charge of Laboratory of Biochemistry, Jefferson Hospital; Assistant Physician, Philadelphia General Hospital. With a Foreword by Hobart Amory Hare, B.Sc., M.D., LL.D. Late Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia. Second Edition, thoroughly revised, 252 pages, illustrated, limp binding. Lea and Febiger, Philadelphia, 1933.

‡Outline of the Cranial Nerves. By John Favill, A.B., M.D., F.A.C.P. Associate Clinical Professor of Neurology, Rush Medical College of the University of Chicago. Cloth, pages 112. The University of Chicago Press, Chicago, Ill., 1933.

Oral Spirochetes and Related Organisms in Fusio-Spirochetal Disease*

ALTHOUGH diseases which are now attributed to the fusio-spirochetal symbiosis can be traced back in medical history even to the time of Hippocrates, our attention has been more centered on them since the World War following which the dissemination of trench mouth has forced our interest in the condition. This volume discusses the biologic and cultural characteristics of oral spirochetes and fusiform bacilli, their symbiosis, and the characteristics of related organisms. Following this there is a clinical discussion of the various forms in which the infection may manifest itself including disease of the oral cavity, the bronchi, the lungs, the eyes, ears, mastoid, the nose and sinuses, the esophagus, meninges, brain, intestines, appendix, skin, and genitalia. In each case clinical characteristics, laboratory identification and therapeutic methods are presented in all necessary detail.

There has been a need for a volume such as this and it may be well recommended.

Criteria for the Classification and Diagnosis of Heart Disease†

THIS small volume, edited by the Criteria Committee of the Heart Committee of the New York Tuberculosis and Health Association, and approved by the American Heart Association, illustrates well the further application of the use of the *Standard Classified Nomenclature of Disease*, reviewed above. There will always be in the specialties need for a special system of classification of those maladies in which the physician is particularly interested. Both of these volumes have been approved by the American Heart Association and each finds its place. The volume under present review is that which would be of particular interest to those interested in cardiology. Its discussion of nomenclature in this particular field goes into much greater detail than the *Standard Nomenclature* but uses essentially the same system. In a large appendix we find very instructive chapters on radiologic diagnosis, involving orthodiagraphic tracings, and on diagnosis in the interpretation of electrocardiograms.

Outline of Preventive Medicine‡

TO MANY the title of this volume will be somewhat misleading inasmuch as it suggests the public health aspects of the subject. The volume is, however, not written from this viewpoint but rather from that of individual preventive medicine. It is a treatise prepared under the auspices of the Committee on Public Health Relations of the New York Academy of Medicine, to which 24 outstanding physicians of New York have contributed, and dealing with the early recognition and prevention of disease in the individual. Starting with a chapter on the principles and methods of the periodic health examination, it next presents a detailed discussion of the incidence of disease. There follows a section on laboratory aids in the early recognition of disease. Next comes a section on preclinical medicine and hygiene, emphasizing particularly the methods that should be applied with the individual patient in the prevention of possible future disease. Most of the remainder of the volume deals with those diseases of medicine, surgery and the specialties in which early recognition or prevention can

be accomplished or in which treatment should be instituted at an early stage in order to prevent the ravages of the later stages. As one contributor writes, "every late case was at one time an early one."

The popularity with which this volume has been received is readily understandable.

Surgical Pathology*

THE third edition of Boyd's *Surgical Pathology* follows the general program laid out in the first two editions. While there is much on microscopic pathology, gross pathology receives ample consideration, a feature which is most essential for good practice of surgery. Illustrations are very abundant and most excellent.

The Medical Secretary†

THIS small volume is presented as a guide for doctors' secretaries and office assistants who have not had special training in this field. The advice given ranges all the way from personal appearance to the proper method of writing manuscripts for publication, and proof correction. The advice given is good and if the medical secretary were to conform to all specifications the doctor's office would run most smoothly and would be spotless. One might feel that a lot of the advice given is already obvious but when one enters some doctors' offices, one realizes that there should be a distinct need for a volume such as this that can be read and assimilated by a really ambitious secretary.

The trouble is that no matter what the qualifications of a doctor's secretary, usually his office reflects his own personality. However, it is entirely possible that a good secretary with a pride in her work and a loyalty to her employer might with the help of this small volume do wonders for a doctor who has failed to realize that the appearance and running of his office really are important from the point of view of the patient.

A third section of the book devoted to medical terminology is really a glossary of the more common medical terms. However, it would be well to emphasize that no medical secretary can get along well without a medical dictionary.

AIR BORNE MOLDS

THE allergist whose interest in air borne pollens takes him to the botanist for aid in the identification of weeds often finds to his surprise that the botanist knows very little of the taxonomy of the ordinary weeds and grasses. His interest both in the classroom and the field has been primarily in the brightly colored flowers and the trees. In the same way the bacteriologist has been only too well acquainted for many years with the air borne molds which are so prone to contaminate culture media, and which, indeed, he speaks of, as the weeds of the bacteriological laboratory.

When it was discovered that molds and yeasts do actually produce morbid lesions not only in the skin but in the internal organs some attention was necessarily given to this form of microorganism, but the pathologist has probably contributed as much to our knowledge in this field as has the bacteriologist. Now, since it has been found that air borne molds may be responsible for disease particularly in the allergic patient, the medical mycologist finds it desirable to acquaint himself more intimately with the weeds of the laboratory. One who has made no special studies in this field might feel that there would be considerable difficulty in finding altogether satisfactory source books for reference. As a matter of fact some very excellent reference volumes are avail-

able which deal with just those phases of the mycology of air borne molds which will be of special interest to the bacteriologist and the clinician. While there are others, some of them more detailed, two most satisfactory books are *Bacteriology* by Buchanan and Henrieci's *Molds, Yeasts, and Actinomyces*. One will rarely have occasion for more detailed information than is contained in these volumes but in such an event Stevens' *Plant Disease Fungi* provides a very complete classification, while *The Aspergilli* by Thom and Church and *The Penicillia* by Thom provides the last word in the classification of these two great groups of molds.

Mold spores are quite ubiquitous as will be vouched for by any bacteriologist, housewife or sailwright. The spore count of molds in the air varies from a matter of hundreds in the outside air to tens of thousands or even hundreds of thousands per cubic yard of air in buildings. They exist in the ground to a depth varying around four feet but are most numerous near the surface. In the earth they serve a useful purpose chiefly by breaking down cellulose into its simpler derivatives and by fixing nitrogen thereby preventing it from leaching out. Sometimes they form an almost symbiotic relationship with the roots of trees, preparing the nutritive substances in the immediate vicinity for absorption by the roots. It is said that the orchid requires its symbiotic mold for existence.

While air borne molds and yeasts are deleterious in certain industries, causing spoilage, in others they are employed to great advantage. In the Orient a mold is used to convert rice into sugar for the manufacture of alcoholic beverages. There, and in this country, *Aspergillus oryzae*, the aspergillus of rice is employed for the manufacture of a diastatic ferment, marketed as Takadiastase. The citromyces and other molds have been used for the manufacture of citric acid. The dark brown sauce used in Chinese restaurants is a product of the fermentation of *Aspergillus oryzae*. Many cheeses are ripened with molds, the most important of which are Camembert and Roquefort, which are ripened through the activity of the proteolytic ferment of a penicillium. Yeasts are employed in the fermentation of wines, beers, and in the making of bread.

Many of the air borne molds have been found to be responsible for allergic coryza and asthma, and these fortunately include most of the common ones such as the mucors, the aspergilli, the penicillia, alternaria. It is of course a logical observation that the commoner air borne molds should be responsible for this type of reaction.

The clinical bacteriologist will as time goes on in all probability develop an increasing interest not only in the pathogenic molds but in the nonpathogens mentioned above.

CLINICAL AND EXPERIMENTAL

THE RELATIVE INCIDENCE OF INTESTINAL PARASITES IN HOSPITAL PATIENTS IN NASHVILLE AND IN RURAL TENNESSEE*

HENRY E. MELENEY, M.D., NASHVILLE, TENN.

RECENT interest in the intestinal protozoa of man in the United States has stimulated the publication of several reports of the incidence of these parasites in cities in various parts of the country. The reports of Williamson, Kaplan and Geiger from Chicago¹ and Andrews and Paulson from Baltimore² give the incidence of all of the protozoa found, while that of Faust³ gives only the incidence of *Endamoeba histolytica*. The data for the intestinal protozoa and helminths for Nashville are given in the present report. If similar reports can be published from time to time from other cities a more accurate index of these parasites can ultimately be secured for the cities of the country as a whole.

The present report is a summary of the routine fecal examinations made in the laboratory of the Department of Preventive Medicine and Public Health of the Vanderbilt Medical School between Jan. 1, 1930, and June 30, 1932.† Of the 2,112 white and negro persons examined, 1,231 were adult medical out-patients and 881 were a miscellaneous group including pediatrics out-patients and in-patients, adult hospital patients suffering from gastrointestinal complaints and a few similar outside patients of private physicians. All of the adult out-patients and most of the other group were persons who could not afford the attendance of a private physician. They came both from

*From the Department of Preventive Medicine and Public Health, Vanderbilt University School of Medicine.

Received for publication, December 14, 1932.

†The author wishes to acknowledge the assistance in this work of Miss Frances Jones, technician in the department, who performed most of the examinations reported.

the city of Nashville and from the surrounding rural districts, and some from other cities. Many who resided in the city had previously lived on farms where they may have acquired their intestinal parasites. Because of this fact no attempt has been made to separate them into urban and rural groups. The results represent the incidence of these parasites from the combined urban and rural population of middle Tennessee.

The technic of fecal examination was as follows:

1. A heavy smear preparation in saline was examined for *Strongyloides* larvae and eggs of helminths.
2. A thin smear preparation in saline was examined for motile protozoa.
3. A salt-flotation test was performed for eggs of helminths.
4. About a cubic centimeter of the specimen was emulsified in tap water by shaking in a 25 c.c. test tube and filtered into a 50 c.c. centrifuge tube through "sheet-cotton" made absorbent by soaking in gasoline. The cotton was washed through with tap water up about 40 c.c., and the filtrate centrifuged at about 1,800 revolutions for one-half to one minute. The supernatant fluid was poured off and a portion of the sediment was examined in iodine eosin solution for protozoan cysts.

5. In cases where the identification of motile amebas or cysts was doubtful in fresh preparations, smears were stained with iron hematoxylin.

Most of the patients received only one fecal examination. When more than one was made it was usually done either to check the previous finding of *E. histolytica* or to follow the effect of treatment, or to make a more thorough search for the parasite in cases suspected of harboring it. This report may therefore be considered on the basis of one examination per person.

Table I shows the results of these examinations. It will be seen that *E. histolytica* was found in 63 patients or 3.0 per cent of the series. Of these 63 patients, only two were suffering from frank amebic dysentery. One other showed trophozoites which were identified as *E. histolytica* by stained

smear and culture, and three others showed both trophozoites and cysts. Only cysts were found in the specimens from the other 57 patients. A few of these were suffering from gastrointestinal complaints but most of them came to the hospital for trouble not apparently associated with amebic infection.

The other protozoa found in this series appeared approximately in the incidence which would be expected if the incidence of *E. histolytica* in the group is taken as a basis for comparison. The incidence of the various helminths is also in accord with what is to be expected in a combined city and rural group in this geographic region. It might be noted that *Strongyloides* larvae were found in fourteen patients, which is more than half as frequently as hookworm eggs were encountered. This indicates that *Strongyloides* is of some importance as a parasite of man in this region even in a city hospital. It will also be noted that all of the helminths as well as *Giardia* had a higher incidence in the in-patient group than in the out-patients. This is probably to be accounted for by the fact that a considerable proportion of the latter group were children, in whom the incidence of both *Giardia* and the helminths is generally higher than in adults.

Table II compares the results of the Nashville summary for protozoa with those from Chicago, Baltimore, and New Orleans. It will be seen that Baltimore seems to enjoy the lowest incidence, Chicago comes second, Nashville third, and New Orleans highest. One would expect the incidence to be progressively higher from north to south and these studies suggest that it is, with the exception of Baltimore. The patients examined by Andrews and Paulson² in Baltimore were a selected group in that they all suffered from gastrointestinal complaints. It is conceivable that such patients sometimes may lose their intestinal protozoa because of an unfavorable environment produced by other pathologic conditions in the gastrointestinal tract. It would be interesting to know whether an unselected series of hospital in-patients or out-patients in Baltimore would show a higher incidence of intestinal protozoa. In the case of New Orleans, one would expect to find a higher incidence of intestinal protozoa there than in the inland cities of the South since New Orleans is exposed to the importation of such infections from the tropics.

A comparison of the incidence of the human intestinal parasites for Vanderbilt Hospital with that for the rural population of eight of the surrounding counties and for the rural population of the State of Tennessee as a whole is given in Table III. The data for the surrounding counties and the state are taken from the recent surveys reported by Melenex, Bishop and Leathers⁴ for the protozoa and by Keller, Leathers and Bishop⁵ for the helminths. This table shows that the incidence of almost every parasite is higher in the surrounding rural area than in the Vanderbilt Hospital patients. This can partly be explained for *Giardia* and for the helminths by the fact that most of the specimens in the rural survey came from school children, in whom the incidence of these parasites is generally higher than in adults. In the case of the amebas, however, this would not apply, since their incidence has been universally found to be higher in adults than in children. The lower incidence of the amebas in the Vanderbilt Hospital patients than in the surrounding

TABLE III

INCIDENCE OF HUMAN INTESTINAL PARASITES IN VANDERBILT HOSPITAL PATIENTS AND IN THE RURAL POPULATION OF TENNESSEE

	PROTOZOA						HELMINTHS			
	<i>E. HISTOLYTICA</i>	<i>E. COLI</i>	<i>E. NANA</i>	<i>TOXAMOEBA</i>	<i>GIARDIA</i>	<i>CILIOMASTIX</i>	<i>ASCARIS</i>	<i>TRICHURI</i>	<i>HOOKWORM</i>	<i>HYMENOLEPIS NANA</i>
Vanderbilt Hospital	3.0	12.7	7.3	3.2	5.5	3.5	2.5	1.0	1.1	1.1
Rural population of eight surrounding counties	9.5	32.0	13.3	4.3	15.0	3.5	16.7	2.5	0.2	1.8
Rural Tennessee as a whole	11.4	32.1	11.9	4.1	14.7	2.9	27.1	7.6	6.8	2.9

rural area is probably due to the fact that the majority of the hospital patients were residents of the city, where excreta disposal is more sanitary, where flies are somewhat less abundant, and where personal hygiene is in general better than in the rural areas.

Table III also shows that the counties surrounding Nashville have an incidence of intestinal protozoa approximately the same as that for the rural population of Tennessee as a whole. In the case of the helminths, however, these counties are considerably below the incidence for the whole state due to the fact that these counties are situated mainly in the "Central Basin" of the state, where the conditions necessary for the transmission of the helminths are less favorable than in some other parts of Tennessee.

It should be remembered that the incidence percentages here reported do not represent the actual incidence in the groups studied. It is estimated that one fecal examination by the technic employed for protozoa will reveal about half of those actually harboring *E. histolytica*. On this basis the actual incidence of this parasite in the Vanderbilt Hospital patients would be about 6 per cent, that in the surrounding rural area would be about 19 per cent and that for the rural population of Tennessee as a whole would be about 23 per cent.

The higher incidence of intestinal protozoa in the rural areas is emphasized particularly in order to focus attention upon the rural population in connection with the problem of amebiasis in the United States.

Andrews and Paulson² in the report of their Baltimore study state, "The incidence of intestinal protozoa in such a civilian" (apparently meaning "city") "group as has been described, is probably more nearly representative of the incidence of intestinal protozoa in residents of the temperate zone as a whole than incidences based upon the previously mentioned surveys" (institutions, troops, mining camps, remote rural districts) "in as much as most of the population of the temperate zone now is concentrated within large cities." This statement leaves the rural population too much out of consideration. The United States Census for 1930 shows that 43.8 per cent of the population of the whole country is rural, and that even in Maryland 40.2 per cent is rural. In the portion of the country designated in the Census as "The North" 32.8 per cent, or nearly one-third of the population, is still rural, and

in the portion designated in the Census as "The South," which includes Maryland, 65.9 per cent, or nearly two-thirds, is rural. It is evident, therefore, that the rural population must still be considered important in determining the incidence of intestinal protozoa in the United States.

Again Craig⁶ in speaking of the amebiasis problem states, "It is undoubtedly true that the vast majority of infections with *Endamoeba histolytica* in this country are acquired through food handlers in public eating places" (institutions, hospitals, hotels, restaurants, etc.). "While in rural communities infection undoubtedly occurs in the home, and while this is also true to a lesser extent in the cities, it is no less true that the great source of infection in this country is the food handler in public eating places." Craig⁶ thus focuses attention on towns and cities as the location of the main problem of amebiasis in the United States. It is undoubtedly true that public food handlers are an important source of infection in cities, and the necessity for their control should not be minimized. On the other hand, the data which have been presented for Tennessee in Table III show that the incidence of amebiasis in the rural areas is three or four times as high as in the city, and it is fair to assume that this does not apply to Tennessee alone. This indicates that the conditions for transmission of the dysentery ameba are much more favorable in the rural districts than in the cities. In the matter of sewage disposal and in the protection of excreta and food from flies, American cities present on the whole much better conditions than most rural districts. Food handlers in public eating places, although they may have no adequate conception of the hygienic handling of food, usually have some degree of supervision which would at least tend to limit the frequency with which they would convey the parasite to the patrons of these places. In the poor rural home, however, where close personal contact constantly occurs, often under the most unhygienic conditions, the opportunities for transmission within the family are much greater. The mother as food handler and nurse, the children constantly playing together, and the fly with its free access to feces and food probably all contribute to the spread of the intestinal protozoa in the family. The long duration of these infections is undoubtedly responsible for their continuation and spread in new family groups by marriage. Frequent visiting between families, and the roaming habits of the fly are probably responsible in the main for transmission from house to house. It seems important, therefore, to focus attention upon the amebiasis problem in rural districts as well as in cities. It must be remembered that the adult population of cities is made up to a significant degree of persons who spent their childhood in rural districts, and that such persons often are employed as domestic servants and public food handlers. It is therefore possible that sources of infection in cities may frequently have their origin in rural areas.

In conclusion it may be said that the results of the examinations in Vanderbilt Hospital indicate that the careful routine examination of fecal specimens from hospital patients anywhere in the United States is well worth the effort in revealing the occasional presence of pathogenic animal parasites, and in discovering a pathologic condition which might not otherwise be diagnosed.

It is undoubtedly true, as Craig⁶ states, that fecal examinations are often more important for a correct diagnosis than some of the other diagnostic measures ordinarily employed as a routine at the present time.

SUMMARY

1. The results of routine fecal examinations for animal parasites in 2,112 hospital patients in Nashville, Tennessee, are reported. The incidence is somewhat higher for most of the intestinal protozoa than is reported for Chicago and Baltimore, but lower (for *E. histolytica*) than is reported for New Orleans.

2. The incidence of most of the intestinal parasites in hospital patients in Nashville is lower than for the surrounding rural area, and lower than for the rural population of Tennessee as a whole.

3. The problem of amebiasis in Tennessee is apparently more a rural problem than an urban problem, though the latter should not be ignored.

4. Careful routine fecal examinations of hospital patients should be employed much more than is the custom at the present time in the United States.

STUDIES IN THE PHARMACOLOGY OF LOCAL ANESTHETICS

VI. COMPARISON OF METYCAINE WITH COCAINE AND PROCAINE ON EXPERIMENTAL ANIMALS

EDWARD E. SWANSON, INDIANAPOLIS, IND.

INTRODUCTION

PRELIMINARY pharmacologic data on certain of McElvain's¹ local anesthetics, piperidine derivatives, have been reported by McElvain and Jones¹ and Rose.² Some of these compounds were submitted to Dr. W. R. Meeker of Mobile, Alabama, for comparative clinical evaluation. Dr. Meeker³ finally selected the compound gamma—(2-methyl-piperidino)—propyl benzoate hydrochloride as the compound which showed promise of a useful local anesthetic.

Since that selection considerable pharmacologic data have been reported on this compound by Coles and Rose⁴; Rose, Coles, and Thompson⁵; Coles and Rose⁶; and Rose.⁷

This article is a continuation of the pharmacologic study of this compound in comparison with cocaine and procaine, particularly, the action of gamma—(2-methyl-piperidino)—propyl benzoate hydrochloride (metycaine) on the perfused heart of frogs, on the blood pressure and respiration of anesthetized and pithed dogs, on the perfused legs of frogs (peripheral vessels), and on the sensory nerve trunk (sciatic of rabbits).

Action on the Perfused Frog Heart.—The hearts of large leopard frogs were used. The perfusion experiments were performed during the months of September and October. The Howell modification of Ringer's solution was used; that is, NaCl 0.7, CaCl₂ 0.026, HCl 0.03, the quantities referring to grams of the anhydrous salts per 100 c.c. of distilled water. This solution had a P_H of 7.2 to 7.3 (colorimetric). The temperature of the solution and of the hearts was kept at 22° C. to 24° C. during the experiments. The hearts were perfused essentially according to the method of Sollmann and Barlow⁸ under constant pressure from the vena cava, the fluid escaping from the wounds and from the inferior end of the vena cava. The perfusion was made by a heart perfusion cannula (Dr. Greene's).

Various dilutions (1:5,000, 1:10,000, 1:20,000, 1:40,000, and 1:80,000) of the local anesthetics, cocaine, procaine, and metycaine, were used. At least 3 frog hearts were used for each dilution.

Cocaine with a dilution of 1:5,000, shows a very marked decrease in rate and amplitude and inhibition of rhythm. This is also observed with dilutions of 1:10,000, 1:20,000, and 1:40,000. A dilution of 1:80,000 produces no change in amplitude and rhythm and only a slight decrease in rate (see Fig. 1).

*From the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Ind.
Received for publication, November 28, 1932.

Procaine, with a dilution of 1:5,000, shows a distinct change in rate and amplitude and an inhibition of rhythm, although not equal to that of cocaine (1:5,000). Dilutions of 1:10,000 and 1:20,000 of procaine produce a slight decrease in amplitude and in rate without disturbance of rhythm. Dilutions of 1:40,000 and 1:80,000 of procaine produce a distinct stimulation, and an increase in amplitude and rate (see Fig. 2).

Metycaine (1:5,000) produces an auricular ventricular block. Metycaine (1:10,000, 1:20,000, and 1:30,000) produces a decrease in amplitude and a decrease in rate without disturbance of rhythm (see Fig. 3). Dilutions of

Fig. 1.—Represents a tracing of a perfused frog heart. The normal heart rate is 48. Following the perfusion of cocaine 1-10,000, the heart shows an A-V block with a marked change in rate.

Fig. 2.—Represents a tracing of a perfused frog heart. The normal heart rate is 54. Following the perfusion of procaine 1-10,000, the heart rate is comparatively unchanged and there is only a slight decrease in amplitude.

1:40,000 and 1:80,000 produce a slight stimulation in 50 per cent of the hearts. Thus, metycaine produces less depressing symptoms on the perfused frog heart than cocaine but is more depressant than procaine.

Action on the Blood Pressure and Respiration of Anesthetized (Ether and Sodium Amytal) Dogs.—Fourteen dogs were used, 6 dogs under ether and 6 dogs under sodium amytal (40 mg. per kg. intravenously). Two dogs were pithed. The vagi were cut in some of the anesthetized experiments. Doses of 1 mg. to 10 mg. per kg. of cocaine, procaine, and metycaine were injected intravenously. In some of the experiments, alternating doses of the local anesthetics were injected in the same animal.

The effects of all three of the local anesthetics on the general circulation are partly central and partly peripheral. Cocaine in small doses (1 to 2 mg. per kg.) causes a distinct increase in blood pressure and a slower pulse rate. In moderate doses (3 to 5 mg. per kg.), the pulse is increased and a rise in blood pressure is observed. This rise in blood pressure and change in pulse rate, with small doses and moderate doses, is less in dogs with vagi cut, and practically absent in pithed dogs. Large doses (5 to 10 mg. per kg.) of cocaine produce in anesthetized and pithed dogs a very great fall of blood pressure and a weak, slow pulse.

Procaine in small doses (1 to 2 mg. per kg.) produces a very slight rise in blood pressure and very little change in pulse rate in anesthetized (ether and sodium amytal) dogs. In dogs with vagi cut or pithed, the rise is absent. The rise, which occurs after the use of small doses of cocaine, is generally higher than the rise produced by procaine. Procaine, in moderate doses (3 to 5 mg.

Fig. 3.—Represents a tracing of a perfused frog heart. The normal heart rate is 42. The arrow shows the change from control solution to a 1-10,000 metycaine solution. Numbers 26 and 30 represent the heart rate following the perfusion of the local anesthetic. There is a decrease in amplitude.

per kg.), generally causes no change or a drop in blood pressure and an increased pulse rate. Procaine in large doses (5 to 10 mg. per kg.) produces in experiments a distinct drop in blood pressure and a slow pulse; however, equivalent doses of cocaine produce a greater drop in blood pressure and a slower pulse.

Metycaine in small doses (1 to 2 mg. per kg.) produces either a very slight rise or no change in blood pressure, and very little change in pulse rate. With small doses (1 to 2 mg. per kg.), the fall of blood pressure predominates in anesthetized dogs (vagi cut) or pithed dogs. Metycaine in moderate doses (3 to 5 mg. per kg.) either produces no change or a slight fall in blood pressure, and a distinct increase in pulse rate. Metycaine in large doses (5 to 10 mg. per kg.) produces a fall in blood pressure and a slow, weak pulse rate. This fall of blood pressure and slow pulse rate with equivalent doses is more than with procaine and less than with cocaine.

The effects on respiration with small doses (1 to 2 mg. per kg.) of cocaine, metycaine, and procaine are acceleration, the degree of acceleration being in the order named. Moderate (3 to 5 mg. per kg.) doses of cocaine, metycaine, and procaine increase the respiration rate, but decrease the amplitude. Large doses (5 to 10 mg. per kg.) of cocaine, metycaine, and procaine cause depression of respiration, the degree of depression being in the order named.

Action on Perfused Frog Legs (Peripheral Vessels).—The perfusion method of frog legs used was essentially that of Trendelenburg's.⁹ The frog was pithed, a cannula (Greene) inserted into the abdominal aorta. The out-flow from the abdominal vein was recorded by the number of drops. The local anesthetics were perfused from a Mariotte bottle through a "Y" connection.

At least 2 or more frogs were used on each dilution. The dilutions used were 1:1,000, 1:2,500, and 1:5,000 of each local anesthetic. Epinephrine 1:40,000 dilution, and sodium nitrite 1:1,000 dilution were used to show vasoconstriction and vasodilatation after the local anesthetic was given. The results of these experiments are given in Table I.

TABLE I
PERFUSION OF FROG LEGS
(Laewen-Trendelenburg Method)*

DRUG	DILUTION	NUMBER OF FROGS	TIME OF MAXIMUM EFFECT	DECREASE (CON- STRICTION)	INCREASE (DILA- TATION)
			minutes	drops	drops
Cocaine	1: 1,000	3	15	4	—
Cocaine	1: 2,500	2	15	3	—
Cocaine	1: 5,000	3	15	—	4
Metycaine	1: 1,000	2	15	0	0
Metycaine	1: 2,500	3	15	0	0
Metycaine	1: 5,000	2	15	0	0
Procaine	1: 1,000	2	15	0	0
Procaine	1: 2,500	2	15	0	0
Procaine	1: 5,000	2	15	0	0
Sodium nitrite	1: 1,000	16	10-30	—	10
Epinephrine	1:40,000	16	10-20	35	—

*Laewen, A.: Arch. exper. Path. Pharm. 51: 416, 1904. Trendelenburg, P.: ibid. 63: 165, 1910.

As shown in Table I metycaine and procaine produce neither constriction nor dilatation. Cocaine produces constriction in dilutions of 1:1,000 and 1:2,500 and dilatation in dilutions of 1:5,000.

Action on the Sensory Nerve Trunks (Sciatic).—The method used is essentially that of Biberfeld and Pototsky and elaborated by Schmitz and Loevenhart.¹⁰ In this study, the technic of the latter was used.

As shown in Table II, a 0.75 per cent solution of metycaine produces anesthesia equivalent to a 3 per cent solution of cocaine and a 0.5 per cent solution of procaine.

Action on Smooth Muscle.—The action of metycaine, cocaine, and procaine on smooth muscle was determined on the isolated intestinal strips of rabbits, isolated bladder of rats, and isolated uteri of guinea pigs and rabbits.

On the isolated intestinal strip of rabbits, the inhibition of normal rhythm is distinct with all three local anesthetics. Metycaine in dilutions of 1:80,000 produces inhibition equivalent to cocaine 1:30,000 and procaine 1:40,000.

TABLE II
MINIMUM EFFECTIVE CONCENTRATION FOR NERVE BLOCKING (RABBIT'S SCIATIC)

DRUG	4		3		2		1		0.75		0.5		0.25

The action of these compounds on the isolated bladder strips of rats shows contraction and a distinct increase in rhythm, the order of their increased effectiveness in dilutions of 1:5,000 and 1:10,000 being metycaine, cocaine and procaine.

In dilutions of 1:5,000 and 1:10,000. these local anesthetics produce a distinct contraction of the isolated uterus of guinea pigs and a contraction and increased rhythm of the isolated uterus of rabbits, their effectiveness in equivalent dilutions being in the same order, metycaine, cocaine, and procaine. Thus, the action of metycaine in equivalent dilutions on smooth muscle is apparently more effective than either cocaine or procaine.

CONCLUSIONS

1. Metycaine produces less depressing symptoms on the perfused frog heart than cocaine, but is more depressant than procaine.

2. The comparative effects on the general circulation and respiration of metycaine are more like procaine than cocaine.

3. Metycaine on the peripheral vessels is more like procaine than cocaine.

4. The action of metycaine on the sensory nerve trunk (sciatic) is two-thirds as effective as procaine and more than three times as effective as cocaine.

5. Metycaine on smooth muscle is more effective than either procaine or cocaine; that is, in equivalent doses, metycaine produces more inhibition of isolated intestinal strips and more stimulation of isolated uterine or bladder strips than either cocaine or procaine.

A FATAL CASE OF SICKLE CELL ANEMIA WITH AUTOPSY FINDINGS*

M. D. HARGROVE, M.D., AND W. R. MATHEWS, M.D., SHREVEPORT, LA.

SICKLE cell anemia, an hemolytic anemia, in which many erythrocytes have a characteristic sickle or crescent shape, was first described by Herich in 1910. Since that time the disease has been reported with increasing frequency by several observers, viz., Washburn, J. E. Cook, J. Meyers, V. R. Mason, V. P. Sydenstricker, J. G. Huch, and others.

It is a familial and hereditary disease confined largely, if not altogether, to the negro race. In those cases apparently white, investigation of the ancestry has usually suggested mixed blood. The condition is congenital, being present at birth, and is probably due to congenital defects in the spleen and blood-forming organs that result in changes in the erythrocytes which predispose them to hemolysis and phagocytosis. The anemia, when present, is due to excessive blood destruction activated, perhaps, by factors that in a normal person would be innocuous. It exists in a latent and active phase. The latent phase presents neither definite symptoms nor physical signs and is recognized only by special blood examination. The active phase presents definite symptoms and physical signs and the characteristic sickling may be seen on an ordinarily stained blood smear.

A number of cases have been reported in recent years, probably the largest series by Sydenstricker. In view of the fact that case reports with autopsy findings are very few, we feel justified in presenting this case with autopsy report.

CASE REPORT

CASE 1.—Colored male, aged twenty-one, was admitted to the hospital on Nov. 27, 1931. At this time he complained of swelling of the entire body, shortness of breath, weakness and vertigo. The onset of the present illness was six months prior to admission, at which time he noticed edema of the feet and legs which gradually extended to the abdomen, face, and arms. Dizziness, weakness, dyspnea, palpitation, and headaches had been troublesome. Occasionally there was moderate epigastric pain brought on by drinking water or eating. On a previous admission to the hospital, September, 1931, a diagnosis of chronic nephritis was made. At this time he was anemic, red cell count 2,030,000, but the phenomenon of sickling was not noted. He remained in the hospital four weeks with subsidence of the edema and improvement of his general condition.

Past History.—He had gonorrhea in 1929 without complications, diphtheria in 1927, pneumonia in 1922, mumps and measles when a small child, frequent attacks of tonsillitis, and several ulcers on the anterior surfaces of both legs six or eight years ago. His mother died at the age of forty-one of Bright's disease. There was no history of blood dyscrasias in the family.

*From Shreveport Charity Hospital.
Received for publication, November 9, 1932.

Physical Examination.—He was a fairly well-developed and nourished colored male with generalized edema and moderate dyspnea. There was an icteric tinge to the sclerae and the tonsils were hypertrophied and cryptic. A few moist râles were heard over the bases of the lungs. There was a systolic murmur heard best at the apex of the heart, not transmitted, and there was no apparent enlargement of the organ. Blood pressure was 150 systolic and 70 diastolic. The abdomen contained free fluid and the liver was palpable two finger-breadths below the costal margin. The spleen was not palpable. There were several scars on the anterior surfaces of the legs about the middle third.

The patient remained in the hospital continuously from Nov. 27, 1931, to Feb. 2, 1932. Treatment was largely of a supportive nature. A suitable donor for blood transfusion could not be obtained either from his family or those who volunteered. Liver extract, ventriculin with iron and iron alone had no effect on the anemia. He ran a low grade temperature up to the last week, then 103.4° F. which we attributed to an exacerbation of the nephritis and bronchopneumonia. He died Feb. 2, 1932.

The report of the laboratory work, made at intervals during his stay in the hospital, is given in Table I.

Necropsy.—The body was that of a well-developed colored male, aged twenty-one, with generalized edema. The pupils were equal, round, and measured 5 mm. in diameter. There was slight jaundice of the sclerae and marked pallor of the conjunctivae. The teeth and gums were in good condition, tongue normal in appearance and consistence and the buccal mucosa was pale. The edema of the upper extremities was quite marked from the elbows downward, including the wrists and hands. The abdomen bulged. The pubic hair was normal in quantity and distribution. The thighs and legs were equal and the skin, which pitted on pressure, was tense and shiny. The posterior cervical and inguinal lymph nodes were palpable. There were several scars on the anterior surfaces of the legs.

Abdomen.—The subcutaneous adipose tissue had a maximum thickness of 5 cm. in the midline anteriorly and presented a pale, gelatinous appearance due to the accumulation of fluid which was given up freely on compression. Several liters of lemon colored, slightly turbid fluid were found in the peritoneal cavity. The peritoneum was smooth and was tinged yellow in color. The liver extended the breadth of four fingers below the costal margin in the midclavicular line, right. The appendix was small, retrocecal, and the serous covering was pale and smooth. There was marked edema of the mesentery and the fat in the omentum, which was rather scant, was a peculiar pale brownish color, and was waterlogged. The mesenteric lymph nodes were enlarged and sectioned surfaces were pale pink. The liver weighed 2250 gm., edges were rounded, and the capsular surface was smooth. Externally it was bluish red in color. Sectioned surfaces bulged slightly and were generally red or brownish red with small patches of yellow here and there. Surfaces were bathed with thin, watery blood. The spleen was found as an elongate, wedge-shaped body lying along the gastrolinal ligament. Its inferior extremity was in contact with the tail of the pancreas while the superior pole did not quite extend to the stomach. Its position was well toward the median line and much lower than the position occupied by a normal organ. It measured 5 and 10 mm. respectively at the upper and lower extremities in width and its greatest thickness was 8 mm. It was 4 cm. long. There were deep wrinkles in the thick, gray capsule. Sectioned surfaces were brownish in color, dry, slightly retracted, and presented a sievelike appearance. The pancreas was normal in size, firm, and the lobules were conspicuous. Surfaces were pink in color. The suprarenals were normal in size, the pigmented zone normal in color and width, and the medullae were pinkish in color. The kidneys were about equal in size and weighed together 430 gm. There was considerable yellowish red fatty tissue about each organ. The capsules stripped easily in cutting resistance and surfaces bulged slightly. The cortices measured from 5 to 9 mm. minute, bulging red points. The pyramids were slightly swollen and, like the cortices and outer surfaces, mottled. The pelvic fat was not excessive and the pelvic lining was smooth and pale. The ureters were free from abnormalities, normal in size, and the lining was

pale. The *urinary bladder* wall measured $1\frac{1}{2}$ cm. in thickness and there were large, clear bullae involving the lining of the organ. On section, these latter were found to represent submucous accumulations of serous fluid. The *prostate* and prostatic urethra showed nothing noteworthy. The *stomach* was normal in size. The rugae were quite conspicuous, and there was diffuse bluish red or dark red color in the lining. There was edema of all parts of the wall of the small and large intestines as well as passive congestion of the lining.

Thorax.—Fluid of the same character as noted in the peritoneal cavity was present in both pleural cavities (amount estimated, 2 liters). The pericardial sac contained 750 c.c. of clear, straw-colored fluid. The *lungs* were small. They were dark red at the bases and posteriorly and were mottled gray and black at the apices and anteriorly. There were old interlobar and apical adhesions on the right. The cutting resistance was increased and sur-

faces were brownish red in color. Rusty, frothy fluid could be expressed from cut surfaces of both organs. There were no areas of consolidation and anthracosis was moderate but diffuse. The main bronchi contained frothy fluid and their lining was pale. The tracheo-bronchial lymph nodes were anthracotic. The heart weighed 410 gm. and was slightly ovoid in shape. There was a milk patch on the anterior surface of the right ventricle measuring 2 cm. in diameter. The epicardial fat was not excessive. There were no gross organic lesions of any of the orifices. The valve leaflets, cusps, and the mural endocardium were tinged

Fig. 1.—Spleen. Arrows point to the extremities of the organ. This represents full size except for $\frac{1}{2}$ cm. removed for section. A portion of the pancreas is above and a section of the stomach wall below.

Fig. 2.—Section from spleen showing fibrosis of the pulp and necrotic malpighian bodies (dark areas). The thickened capsule is noted as infoldings (low power).

yellow. The myocardium was brownish red in color and fairly firm in consistence. The maximum thickness of the left ventricular wall at the base was $2\frac{1}{2}$ cm. Rather conspicuous scars were noted in the left ventricular wall at its base. The lining of the coronary arteries and aorta was smooth and pale.

The convolutions of the brain were moderately flattened, and there was an excess of fluid in the subarachnoid space.

The bone marrow in the upper thirds of the tibiae and humeri were red.

Microscopic Examination.—Tissues were fixed in formaldehyde and paraffin sections stained with hematoxylin and eosin.

Heart.—There was moderate perivascular fibrosis which radiated between the adjacent muscle bundles. In addition, there were focal areas of degeneration with beginning connective tissue replacement. Relatively large areas of scarring which extended out to the epicardium were noted in some of the sections. There was diffuse engorgement of the small vessels. In places the nuclei were quite large.

Lungs.—There was an increase in the peribronchial and finer connective tissue about the alveoli. The alveolar septa were quite thick, due both to the feature mentioned above (fibrosis) and engorgement of the capillaries. Red cells were present in many of the alveoli as well as "heart failure cells." Many of the alveoli contained pink staining serous coagulum. The interstitial element was heavily laden in places with black pigment.

Aorta.—The aorta presented nothing noteworthy.

Spleen.—The capsule was thick and dense, and there were convolutions which extended deeply into the organ, almost meeting similar infoldings of the capsule from the opposite

Fig. 3.—Section from spleen (high power).

side. Trabeculae were not identified. The pulp was completely replaced by dense, relatively acellular but somewhat loosely arranged connective tissue. This latter separated dark staining oval or oblong areas in which clear-cut cellular structure was conspicuously absent. These appeared to be composed of the necrotic remains of the malpighian corpuscles. In the centers of most of the dark staining areas was a less dense oval space containing either homogeneous pale staining material, old erythrocytes or dense connective tissue. Surrounding these was a darker zone of varying width composed of débris of necrotic cells and, in not a few instances, old erythrocytes and brown pigment.

Liver.—The capsule was slightly thickened. The central veins and adjacent portions of the sinusoids were engorged with erythrocytes, while the sinusoids at the periphery of the lobules showed this feature less conspicuously. The cell cords were relatively narrowed. There was diffuse hemachromatosis and cloudy swelling of the hepatic cells as well as fatty change in places. There was a varying amount of fibrosis, lymphocytic and, to a less extent, eosinophilic infiltration about the portal canals. In some instances fibrous strands radiated for some distance replacing the degenerated parenchyma. In such areas regeneration of bile capillaries was noted.

Kidneys.—The glomeruli showed a variety of changes which represented stages in the same progressive process. Proliferation of the subcapsular cells with formation of crescents or circles which in many instances showed fusion, fibrosis and hyalinization was a conspicuous feature. Many of the glomerular tufts were small and in some instances presented as small fibrous or hyalinized balls. Adhesion of the tuft of capillaries to the thickened capsule of Bowman was present in many places. Interstitial fibrosis and infiltration with lymphocytes, plasma cells, and an occasional eosinophile, particularly around the glomeruli showing advanced change, were widespread in the cortex. The tubules were dilated in many instances and contained a serous coagulum or hyaline casts. The tubular epithelium showed cloudy swelling, fatty degeneration and necrosis, not diffuse. The capillaries were generally engorged and the glomeruli, normal in appearance, completely filled the subcapsular space in most instances.

Pancreas.—Other than diffuse congestion and cloudy swelling, this organ showed nothing noteworthy.

Suprarenals.—Postmortem change.

Fig. 4.—Wet preparation of blood showing sickling.

Lymph nodes.—The mesenteric and inguinal nodes showed diffuse fibrosis. There was an accumulation of large, pale macrophages as well as an occasional eosinophile and neutrophile in some of the sinuses. A few eosinophiles were present diffusely in the cortex and pulp cords.

Summary of Gross and Microscopic Diagnoses.—Chronic passive congestion, edema and anthracosis of lungs; chronic pleuritis, right; chronic interstitial pneumonia; chronic fibrous myocarditis with moderate hypertrophy of heart; milk patch on anterior surface, right ventricle; cloudy swelling, hemachromatosis, fatty change, passive hyperemia and slight perilobular fibrosis of liver; necrosis and atrophy of spleen; passive hyperemia and cloudy swelling of pancreas; subacute and chronic productive capsular glomerulonephritis; chronic lymphadenitis; hypertrophy of bone marrow; chronic hypertrophic gastritis; anasarca; hydrothorax, bilateral; hydropericardium; ascites; jaundice; anemia.

DISCUSSION

This patient presented the characteristic findings of sickle cell anemia with an associated nephritis. The blood examinations showed the characteristic anemia, sickling, and leucocytosis. In addition, a decrease in the fragility of the erythrocytes was noted, no hemolysis occurring in dilutions which began with 0.5 and ended with 0.28. In five latent cases, detected by routine examination of wet preparations on 137 negro patients, delayed fragility was also noted, hemolysis beginning in dilution 0.38 and incomplete in dilution 0.28.

The characteristic pathology appears to be confined to the spleen and bone marrow. The findings in neither have been uniform which, perhaps, is best interpreted by assuming that different stages of a progressive process were encountered. There may be enlargement or atrophy of the spleen. Congenital malformation of the sinuses with free escape of blood into the pulp and the formation of blood pools around the malpighian bodies are probably characteristic of the latent phase and the early or intermediate stages of the active form. Marked atrophy of the organ with complete fibrosis of the pulp and necrosis of the few remaining malpighian bodies, as in our case, probably indicate long duration of active disease.

The bone marrow picture is that of chronic infection or injury with compensatory hyperplasia. Here again, the findings have not been constant. In our case there was simple hyperplasia of the marrow, while in Graham's case, there was chronic productive inflammation with centrifugal involvement of the bone. Chronic osteomyelitis, periostitis, leg ulcers, and even osteitis have been observed radiologically and at necropsy, but there may be fatal cases with atrophy of the spleen and the terminal complications such as nephritis and pneumonia which show none of these.

BLOOD CATALASE IN HEART DISEASE*

1. PRELIMINARY REPORT

JAMES C. HEALY, M.D., AND HENRY BAKER, M.D., BOSTON, MASS.

IN 1863 Schoenbein¹ described the catalytic effect of some substance in vegetable and animal tissues which liberated oxygen from a solution of hydrogen dioxide. The activity of this principle could be diminished by the addition of weak acids, heat, and other anticatalytic agents and because of its evident biologic nature he considered it to be an enzyme and called it catalase. From close observation of the type of reaction it has been claimed² that this enzyme in tissues is relatively inactive but that in the first phase of its reaction with the dioxide it becomes an active catalase. Furthermore, its activity is in direct proportion to the hydrogen ion concentration of the solution, rising up to a certain point and in inverse proportion to the temperature within certain limits, becoming less active as the temperature rises. The optimum temperature for the reaction is about 10° C., but temperatures up to 40° C. cause little, if any, inactivation whereas at 58° C. about 25 per cent catalytic action is lost.^{4, 5, 6, 7}

In testing for catalase different grades and brands of commercial hydrogen dioxide solution have given varying yields of oxygen with the same tissue but the errors could be eliminated by neutralizing the solution with sodium hydroxide.⁸ Margolis and his coworkers⁹ found that high concentrations of hydrogen dioxide destroyed catalase in tissues and drew attention to the necessity of proper dilution.

The function of tissue catalase has been a subject of considerable dispute and its true value is still unappreciated. The majority of authors feel and have shown by more or less conclusive deductions that it is an important metabolic factor, particularly in intracellular oxidative processes. Burge⁹ found that the catalase content of tissues is dependent on or proportionate to the metabolism and varies with the respiratory exchange. A high protein diet, as one would expect from its specific dynamic action, has been shown to cause an increase in catalase content,^{10, 11} and after alcohol ingestion a similar rise has been observed.¹⁴ Experimentally a fall in tissue catalase has been produced by starvation,¹² castration, thyroidectomy,¹³ and to a less extent by pancreatotomy.

Clinically, changes in catalase content have been recorded in many diseases. In primary anemia, a rise has been observed whereas in cachectic diseases,¹⁵ cancer, hemolytic anemias, febrile diseases and pulmonary tuberculosis,¹⁶ there is a distinct fall. Its association with the metabolic rate has been noted further in many experimental and clinical observations as in the re-

*Received for publication, November 15, 1932.

ported associated variations of both in the same individual during different parts of the day,¹⁷ the occurrence of less tissue catalase in young kittens than adult cats,¹⁸ and the 70 per cent increase in the blood during a mountain sojourn as compared with an increase of 38 per cent in the erythrocytes.¹⁹ Varying favorably with the differences in metabolic rates, Alexeeff, et al.,²⁰ have found that the catalase content of male blood exceeds that of the female by 10 per cent. Robben,²¹ however, challenges this metabolism theory of catalase function and shows that catalase added to muscle exercised no effect on the respiratory exchange. Moreover, Stehle^b found that catalase content of blood is directly proportionate to the concentration of red corpuscles, and is not related to biologic oxidative processes. Furthermore, in a large number of experiments on protein feeding, he failed to produce an increase in catalase except in one case. In order of quantity catalase has been found and measured in the following tissues: blood, kidney, liver, spleen, lungs, heart, brain, and muscles.²² Blood serum contains no catalase,²³ corpuscles suspended in isotonic solution fail to give the typical reaction with hydrogen dioxide, but laked erythrocytes liberate oxygen from the reagent,²⁴ the intensity of reaction varying with the number present.²⁵

Catalase determinations have been reported in human organs both in health and disease. Diseased kidney has a decreased value, the content being less with the more extensive pathology.^{26, 27} The rôle of erythrocytes is emphasized in the study of a pneumonia lung. During the stage of red hepatization, the catalase activity is increased over that of a normal lung and in a hemorrhagic infarct it is enormously increased. On the other hand, during gray hepatization, the pulmonary catalase is decreased. During ether or chloroform anesthesia, the catalase content of all tissues is decreased,²⁸ asphyxia having the same effect.²⁶ There is no appreciable change in diabetes, senility, eclampsia,²³ and there is no relation between change of heart rate and blood catalase.²⁹ Sollmann³⁰ investigated the catalase activity of the oral mucous membrane and found that there was no diagnostic change in the various forms of sore throat.

In this study, the authors make no attempt to explain the rôle of blood catalase, but wish to point out the changes in heart disease and their diagnostic value.

TECHNIC

In our work, several methods were tried, many being complicated. The set-up which proved to be the simplest to operate and the most efficient is that described by Hawk and Bergheim³¹ with one minor modification by us. Most of the pathologic cases were seen at the Cardiac Clinic of the Boston City Hospital between ten and eleven o'clock in the morning, and all the blood specimens were taken at that hour in the order of the patient's appearance at the clinic and without knowing the diagnosis. Each patient was questioned about the content of his breakfast; those having had meat or eggs were tested on the following day when protein was eliminated from the meal. Complete blood examinations were done when indicated. After the oral temperature and pulse rate were recorded, blood was drawn into a special calibrated white

blood corpuscle diluting pipette up to the five mark from a puncture wound in the ear lobe. The pipette was then filled with distilled water and the contents transferred to a small test tube, several distilled water washings of the pipette being added to the laked blood. This was then corked and stored with the other morning's samples in the laboratory at 16° C. for twenty-four hours.

To 85 c.c. of a 3.5 per cent solution of hydrogen dioxide,³² 15 c.c. N/10 sodium hydroxide solution were added, both reagents having been stored at the same temperature as the blood. The above mixture was made up each day the tests were done and prepared afresh for each ten blood samples.

The diluted laked blood was introduced into a 250 c.c. distilling flask and 10 c.c. of neutral hydrogen peroxide solution added from a Johnson modified burette, the flask being rotated until a reaction became apparent, and the oxygen liberated collected over water by displacement in a graduated cylinder. After an arbitrary time limit of five minutes, from the moment the hydrogen dioxide solution was introduced, the number of cubic centimeters oxygen liberated was read directly from the cylinder.

One hundred thirty-six blood samples from the same number of apparently healthy individuals were examined in this way and the normal range was found to be 10 to 15 c.c. oxygen. One-fifth of that number and several of the pathologic cases listed in the table were checked on different days, the figures agreeing within 5 per cent.

Four hundred and twenty-nine cases were studied and the amounts of oxygen liberated by the individual bloods carefully checked. When a blood caused a 19 c.c. yield, it was repeated to be certain that it was not a borderline case and its proper classification ascertained. The average normal figure was found to be about 15 c.c., thus putting all the normal cases in the 10-20 group.

In the last two groups of Table I, we find practically all the cases of rheumatic and scarlatinal endocarditis. There were 116 cases of mitral and aortic valvular disease of rheumatic etiology in the third group, a few of which were decompensated. All these were felt to be inactive affections as determined by the general clinical picture of each case and observation over a period varying from weeks to years. Seven others in this third group were found to be active, some at first examination and others after close study, the average yield being 29 c.c. in these. In the final group 18 cases of active rheumatic endocarditis gave the typical high result, two having been thought to be sub-acute bacterial endocarditis but the diagnosis was never finally established.

The three septicopyemia cases fall into the first two groups and are sharply differentiated from the rheumatic endocarditis of the latter groups.

Thirteen cases of scarlet fever are listed in the lower range, all having no organic heart complications. Six other cases, known to have a heart lesion arising as a complication of the fever fall into the class of rheumatic endocarditis, two being definitely active. The results in these cases are of particular interest when we consider the newer theory of relation between rheumatic fever, chorea, tonsillitis, and scarlatina. In 1899 McCollum³³ reported three cases of endocarditis as a complication of scarlet fever in a series of 1000 consecutive cases. Broadbent³⁴ reported endocarditis in 0.58 per cent of scarlet

fever complications while Reinhard³⁵ found it in only one case of his series. Nobecourt³⁶ believes that the same etiologic agent in scarlet fever, rheumatic fever, chorea, and tonsillitis cause similar heart lesions, and Fahr,³⁷ from his pathologic studies, affirms his opinion of the general similarity of heart affections in scarlet fever and rheumatic infection. Sutherland,³⁸ on the other hand, believes that an attack of scarlet fever sensitizes the endocardium in individuals susceptible to rheumatic infection and that such infection is latent in those cases becoming active in the presence of scarlatina. Swift³⁹ has classified the heart complications of scarlet fever as follows:

1. Toxic, similar to those complicating diphtheria and occurring in the first week of the disease. They are due to the action of the disease. They are due to the action of the toxin on the myocardium.
2. Septicopyemic, malignant and rare.
3. Allergic, which occurs in the third and fourth week of the disease and is due to an acquired hypersensitiveness to the streptococcus or its toxin.

Despite the fact that the number of cases is small, the blood reaction in scarlatinal endocarditis closely resembles that of rheumatic etiology and further study is warranted.

In five instances the catalase content of blood proved to be of no diagnostic value. The first case was that of a decompensated mitral stenosis in which the yield was only 10 c.c. The second, an epileptic, yielded 26 c.c., an

infectious arthritis 21 c.c., aortic aneurysm 24.5 c.c., and a bronchopneumonia 38 c.c. The last case was that of a prolonged migratory bronchopneumonia in which there were no heart complications. These determinations were repeated with identical results.

In the early part of our work, we attempted to correlate our catalase values with the valve affected, intensity of physical signs, degree of dyspnea and other symptoms, grade of hypertrophy, but so far have found no relation to these factors.

At the present, our knowledge consists in the recognition of normal catalase values in human blood from 0-20 c.c. A value of 21-30 indicates valvular disease, the final diagnosis being dependent on the entire clinical and laboratory picture. At about 26, the lesion is probably active and over 30 certainly active. This was illustrated in the case of a medical student, twenty-six years of age, who first came under observation in October, 1931. At that time he was examined routinely on admission to the school and a tachycardia (rate 110) noted. He complained of nervousness but otherwise felt well. Ten years before he had severe pains in his legs and was obliged to stay in bed for two weeks. From that time until his admission to medical school he had frequent sore throats but no return of joint pains and he had been frequently examined in school and college. Aside from the rapid pulse and cryptic tonsils the examination was normal. A month later a basal metabolism rate was advised because of the nervousness and persistent tachycardia. Two tests were performed, both being normal.

The patient was seen by one of the authors in December, 1931, and early signs of heart disease were noted. The pulse rate was 96, rhythm regular, heart not enlarged to percussion, but there was a short blowing systolic murmur at the apex, intensified by exercise and transmitted to the axilla. The first sound at the apex was short and of a snapping character and the second sound in the pulmonic area was reduplicated. A blood catalase test was performed, the result being 44. He was advised to enter a hospital but refused and was not seen again until Jan. 20, 1932. Then he complained of weakness, pallor, palpitation, and precordial pain. Examination of the heart revealed a long crescendo presystolic murmur and snapping first sound at the mitral area. The pulmonic second sound was greatly accentuated. Apical and radial pulse rates were 126. An electrocardiogram showed a P-R interval of 0.20 second and a QRS complex of 0.08 second duration. The blood catalase finding was 41. The patient was hospitalized and given large doses of salicylates together with complete rest. An orthodiagram revealed no heart enlargement.

The blood catalase quantity dropped to 28 c.c. oxygen yield over a period of two weeks and the pulse rate to 86. Tonsillectomy was performed on the fifteenth day and the patient discharged to his home on the sixteenth day after entry. At that time P-R interval was 0.16 second and the duration of the QRS complex 0.06 second.

The authors were unable to get in touch with the patient again until March 20, 1932, at which time he was obviously an ambulatory cardiac. He complained of intermittent attacks of fever, palpitation, dyspnea, precordial

pain and weakness. Physical examination of his heart revealed a rate of 100, enlargement to percussion, a long harsh diastolic murmur and short first sound at the mitral area.

The results of a blood catalase test were 40.5 c.c. and this dropped to 30 c.c. after a week's rest at his home and in May, 1932, he was seen again with the same symptoms and signs and a catalase value over 40 c.c.

In this particular case the authors feel that an earlier diagnosis might have been made by a catalase test when his tachycardia was first observed. The fact that a relatively short period of bed rest caused symptomatic and actual improvement as shown by the change in catalase content of his blood should suggest that a longer treatment would have arrested the lesion and probably brought the catalase value below 26.

The authors were fortunate to obtain permission to study the blood reaction and use the record of two patients who came to necropsy.

CASE 1.—This twenty-three-year-old white female entered the Boston City Hospital Jan. 12, 1931, complaining of easy fatigue ability, shortness of breath and swelling of the ankles of several years' duration. There was a history of rheumatic fever several years before and she had had a crop of red, tender nodules on her legs two months before admission, which persisted for five weeks. The patient was kept in bed for three weeks, during which time the temperature was normal and she was sent home with a diagnosis of rheumatic heart disease. On March 3, 1931, she was readmitted to the hospital. Fever was the only complaint at this time and had persisted since February 21, when she had a mild sore throat, chilly sensations, and pains and swelling of the wrists and hands. Examination revealed a fairly well-developed and nourished, young female, not acutely ill. The eyes, ears, nose, and throat were normal. According to the record, physical examination of the heart revealed that the point of maximum intensity was in the fifth interspace outside of the midclavicular line. There was a loud systolic murmur at the apex which was transmitted to the axilla; the first sound at the mitral area was loud and snapping and the second sound at the pulmonic area accentuated. The blood pressure was 110/70. The lungs and abdomen were normal, and there was no swelling of the joints. Examination of the nervous system revealed no abnormalities.

Laboratory Examinations.—Urine and sputums were normal. The white count was 15,600 on admission. Chest plates showed a mass to the right of the superior mediastinum, and an enlarged heart with a mitral deformity. Repeated blood cultures were negative except for one in which there was a growth of *Streptococcus viridans*. Late in her illness, the authors determined the catalase content of her blood and found it to be 18.5. This result, in view of the above studies, was not consistent with a diagnosis of subacute bacterial endocarditis. The catalase reactions repeatedly remained normal.

Two weeks after admission, the chart showed a wild, swinging temperature ranging from 97° to 104°, until demise Jan. 19, 1932. Many roentgenograms of the chest were taken, were interpreted variously, and did not aid in clarifying the situation. Except for small, red, tender, skin nodules cultures from which showed *Staphylococcus aureus* which kept recurring and the development of enlarged swollen and tender knees, the condition of the patient did not change much over a period of several months. Death occurred suddenly.

Clinical Diagnosis.—Subacute bacterial endocarditis, acute dilatation.

Postmortem Examination.—The body was that of a poorly developed, poorly nourished white female. There was marked swelling of the first phalanx of the middle finger on each hand. Both knee joints and the right ankle joint were markedly enlarged. Over the anterior surface of the right thigh were several round, white scars about 1.5 cm. in diameter.

Pleural Cavities.—The left pleural cavity was negative. The right pleural cavity in the region of the lower lobe was obliterated. The pleuras were thickened and on cross-section varied in thickness from 8 mm. to 2 cm. Patches of soft, yellow material, 0.3 to 1 cm.

in diameter were scattered through the dense gray tissue representing the pleuras. In the region of the eighth rib at its point of juncture with the vertebral column, situated behind the pleura was a pocket of thick, yellow fluid 4 cm. by 2 cm. The ends of the ribs in this region were eroded.

Pericardial Cavity.—Negative.

Heart.—Weight 410 gm. There was a moderate degree of enlargement. The muscularis was dark red and firm with no gross areas of scarring or softening. The endocardium was smooth and *all valves were negative*. Both coronary arteries were patent throughout. There were no congenital anomalies of the heart or of the pulmonary artery or aorta.

Spleen.—Weight 220 gm. This organ was enlarged. The capsule was thin and wrinkled. Section showed a dark reddish purple parenchyma of soft consistence. The cut surface scraped with ease.

Joints.—On opening the right knee joint, a quantity of thick, gray fluid containing many yellowish gray flakes, was discharged. There was about 200 c.c. of this fluid. The synovial surfaces were fibrin coated. The synovia was soft, red, and thickened. It was closely adherent to the cartilage over the medial condyle of the femur. The semilunar cartilages could not be identified. The joint cartilage was smooth and glistening, except over the area of attachment to the synovia.

ANATOMICAL DIAGNOSES

Old pleurisy with abscess formation.

Retropleural abscess.

Purulent arthritis.

Cardiac hypertrophy.

Chronic passive congestion of the liver.

Enlargement of the kidneys.

In this case the low blood catalase coefficient was the only finding inconsistent with a clinically typical picture of subacute bacterial endocarditis, and the only antimortem finding consistent with the absence of an endocarditis at autopsy.

CASE 2.—J. G., a forty-seven-year-old male restaurateur was admitted to the Boston City Hospital in November, 1931, complaining of febrile attacks of five months' duration. Symptoms of fever, weakness, and loss of weight came on after a tonsillectomy in June, 1931. He had lost about sixty pounds of his weight during this time. Physical examination was entirely negative aside from the intermittent fever. Roentgenograms of chest, gastrointestinal system and skeleton were normal. The Kahn, Widal, agglutination tests for tularemia, red corpuscle count, and hemoglobin tests were normal. Blood cultures and repeated searches for blood and intestinal parasites were negative. There was a persistent leucopenia, the count varying from 2,700 to 4,400. The differential count was normal. Blood catalase determinations averaged 16 thus excluding the possible diagnosis of rheumatic heart disease or subacute bacterial endocarditis. Quinine by mouth and arsphenamine intravenously were finally tried empirically. The patient improved and was discharged during a remission in January, 1932.

The fever recurred and he was admitted to another hospital for two weeks where no diagnosis was made. He reentered the Boston City Hospital in March, 1932, complaining of fever for three weeks, vomiting and diarrhea following an injection of arsphenamine. Physical examination at this time revealed further loss of weight, an enlarged liver and spleen and areas of brownish pigmentation on chest and back. He had convulsions on the third day which became more frequent and severe. The patient died on the fourth day after reentry.

Clinical Diagnosis.—Unexplained fever; ? subacute bacterial endocarditis.

Anatomical Diagnosis.—Lymphoblastoma involving liver, spleen, bronchial and hypergastric nodes. Focal necrosis in liver.

SUMMARY

We offer herewith:

1. Some considerations relative to the catalase reaction.
2. Our technic and standardization.
3. Results in 429 cases.
4. Suggestions as to the relationship of scarlet fever endocarditis to rheumatic heart disease.
5. In a small series (6 cases) of diphtheria with definite heart damage, the catalase was normal.
6. Three specific cases: (a) Early diagnosis and course of activity by the catalase test. (b) Case clinically resembling rheumatic heart disease with subacute bacterial endocarditis (including one positive blood culture, *Streptococcus viridans*). Catalase was normal. (c) Doubtful case clinically. Negative evidence by means of test.

CONCLUSIONS

1. The determination of blood catalase is of value in making a diagnosis of rheumatic heart disease especially in doubtful cases.
2. It is of help in determining the activity or inactivity of a valve lesion.
3. Study of the blood catalase in active rheumatic endocarditis will aid in determining the length of time required for treatment.

A STUDY OF BLOOD CALCIUM AFTER THE ADMINISTRATION OF SODIUM OXALATE TO NORMAL AND THYROPARATHYROID-ECTOMIZED CATS*

WILLIAM SALANT, M.D., WILLIAM M. PARKINS, PH.D., AND LILLIAN E. SHEPPARD, M.A., LONG ISLAND, N. Y.

SINCE oxalate forms an insoluble compound with calcium, a number of investigators were led to study its effects on calcium in the body, and, although their results were obtained in experiments on different animals and by different methods, they all agreed that the administration of soluble salts of oxalic acid was accompanied by deprivation of calcium from the tissues. According to Sarvonat and Roubier,¹ a considerable loss occurred in the soft parts as well as in the skeleton when oxalate was given to guinea pigs, in sufficient amounts, for several days. Luithlen² reported the elimination of large quantities of calcium in the urine of rabbits after the administration of oxalate, and Gross³ found that the calcium content of dog's blood, after subcutaneous injections, was reduced 50 per cent, while Vines⁴ obtained similar results in experiments on rabbits after the administration of ammonium oxalate. McCrea⁵ reported that blood calcium was likewise decreased in cats that received sodium oxalate, and Gley and Kokas,⁶ in studies on rabbits and cats, and more recently Chiao Tsai and Fong Yen Hsu,⁷ in experiments on dogs, furnished additional data that oxalate lowered the calcium level in the blood. With the exception of Vines and the Chinese investigators, no attempt has, as far as we know, been made to determine the speed of recovery, nor have any observations been reported on the effect of the amount, the frequency or the method of, administration of oxalate on the concentration of blood calcium. As we found that a relation existed between calcium depletion, produced by oxalate, and pharmacologic reactions,⁸ a study of its action, with special reference to those factors, was considered particularly advisable. The present investigation was, therefore, undertaken and observations were made on the changes in blood calcium produced after the subcutaneous or intravenous administration of different amounts of sodium oxalate, attention being directed also to the duration of the effect and to the influence of smaller doses when given for a period of several days. Owing to the rôle which the parathyroids play in calcium metabolism, experiments were also carried out on the effects on blood calcium produced by oxalate after their removal, for the results under these conditions might throw some light on those obtained when it is given to normal animals.

*From the Biological Laboratory, Cold Spring Harbor. Long Island, N. Y.
Received for publication, December 5, 1932.

Methods.—Cats, which were kept on a uniform diet of salmon, bread and milk with water ad libidum, were the subjects of the experiments. As indicated above, sodium oxalate was given subcutaneously and also intravenously, in which case urethane anesthesia was sometimes employed. The doses administered by intravenous injections were 10 mg. sodium oxalate per kilo about ten minutes apart, and the amounts administered subcutaneously were 20 mg. per kilo every twenty or thirty minutes. Blood calcium was determined by the Kramer Tisdall⁹ method, the blood for analysis being usually drawn from the heart, but it was sometimes obtained from the femoral artery, instead. In all cases, calcium was determined before as well as after oxalate, and in thyroparathyroidectomized animals analyses for calcium were made before the operation and also about ten to thirty minutes before the injection of oxalate was begun. In some experiments more than one analysis were made in the interval between extirpation of the gland and the administration of oxalate. The operations, for the removal of the thyroid and the parathyroid, were carried out under proper aseptic precautions, with ether as the anesthetic. Oxalate was given intravenously, usually within two days, but a longer interval was sometimes allowed to elapse.

Results.—Although depression of the calcium level of the blood by oxalate, was produced by subcutaneous as well as by intravenous injections, the effect, caused by the two methods of administration, varied considerably. One hour after the subcutaneous injection of a dose of 20 mg. sodium oxalate per kilo,

practically no effect on blood calcium was observed in three out of five experiments, while the remaining two showed a decline of 5 and 8 per cent (Table I). The results were quite different when this dose was repeated for several days. While very marked changes in the concentration of calcium after the second dose were seldom observed, the fall being 6 to 8 per cent in 4 experiments and 19 per cent in only 1, the decrease of calcium in the blood was much greater after subsequent injections. The maximum diminution was 16 and 25 per cent after the third, 15 to 19 per cent when the fourth dose was given, 18 and 21 per cent after the fifth. We also observed that the depletion was progressive, the decrease of calcium reaching a maximum one hour after the third, fourth, and fifth injections, in different experiments, and, in one case, this was noticed even twenty-five and one-half hours after the fourth dose. Illustrative of the cumulative effect of oxalate was one experiment, in which no change was observed after the first dose, but the drop in the concentration of calcium was 19 per cent after the second, and 25 per cent after the third injection, and another, in which the first dose was likewise without demonstrable disturbance of blood calcium, the decrease was 6, 13, and 19 per cent after successive injections. Replacement apparently occurred as well as loss, as about twenty-four hours after the injection the calcium content of the blood was appreciably greater than it was one hour after the same amount was given, and in 3 experiments the effect of oxalate on blood calcium was negligible at the end of thirty hours (see Table I).

When the amount of oxalate was increased to 40 mg. per kilo, which was given subcutaneously in divided doses, and the blood was drawn one-half to one hour later, the fall of serum calcium was 2.5, 5.1, and 13 per cent in 3 experiments, but, in 2 others, it was 25 and 26 per cent. The results were not greatly different, in some experiments, with 80 mg. oxalate per kilo, as the decrease of calcium, half an hour after the injection, was 11 to 20 per cent in 4 experiments, but in 2 it was 36 and 37 per cent. The calcium content of the blood, four hours after the administration of these amounts of oxalate, failed to show any change from that previously observed, in some experiments. A distinct improvement occurred, however, in others, calcium showing a rise of 8 to 13 per cent above the previous level. On the other hand, a still further depression sometimes occurred, for in one experiment, with 40 mg. oxalate per kilo, the decrease of calcium was 25 per cent one hour after the injection and 32 per cent three and one-half hours later. Analysis of the blood within twenty-three to twenty-nine hours, after the administration of 40 mg. oxalate per kilo, indicated that the blood calcium regained its normal level in some cases and was 12 and 16 per cent below in 2 others. The changes were even more irregular after 80 mg. oxalate per kilo, the decrease of blood calcium in 2 experiments being greater on the day following than it was a few hours after the injection, and in one of these, depression of the calcium level continued as the concentration, fifty hours after oxalate was given, was less than on the previous day. In 4 other experiments, in which the fall of blood calcium half an hour after the administration of this amount of oxalate was 16 to 20 per cent, no significant change occurred in the course of about twenty-

four hours. But in 2 experiments in which, as mentioned above, pronounced depression of the calcium level was produced, the decrease amounting to 36 and 37 per cent half an hour after the injection of oxalate, the diminution of blood calcium was only 6 and 9 per cent about twenty-one hours later. To sum up the results obtained in this series of experiments, it may be stated that complete recovery was observed in about twenty-four hours only when 40 mg. oxalate per kilo were given, while in experiments with double this amount, the normal level was not restored until a period of forty-five to fifty-one hours after the injections was allowed to elapse.

*Tables II, IV, and V contain only some of the experiments given under the respective headings.

Wide variations in the decrease of blood calcium also occurred after intravenous injections even when the same amounts of oxalate were given. Six to ten minutes after the injection of 20 mg. sodium oxalate per kilo, the diminution of blood calcium was 10 to 28 per cent in 4 experiments, and, exceptionally, these differences were greatly increased, for while we found that, in one experiment, the fall, after one hour, amounted to 3.6 only, and the concentration of serum calcium in another was decreased 6 per cent, in a third it was 43 per cent. It may be remarked, in this connection, that the blood cal-

practically no effect on blood calcium was observed in three out of five experiments, while the remaining two showed a decline of 5 and 8 per cent (Table I). The results were quite different when this dose was repeated for several days. While very marked changes in the concentration of calcium after the second dose were seldom observed, the fall being 6 to 8 per cent in 4 experiments and 19 per cent in only 1, the decrease of calcium in the blood was much greater after subsequent injections. The maximum diminution was 16 and 25 per cent after the third, 15 to 19 per cent when the fourth dose was given, 18 and 21 per cent after the fifth. We also observed that the depletion was progressive, the decrease of calcium reaching a maximum one hour after the third, fourth, and fifth injections, in different experiments, and, in one case, this was noticed even twenty-five and one-half hours after the fourth dose. Illustrative of the cumulative effect of oxalate was one experiment, in which no change was observed after the first dose, but the drop in the concentration of calcium was 19 per cent after the second, and 25 per cent after the third injection, and another, in which the first dose was likewise without demonstrable disturbance of blood calcium, the decrease was 6, 13, and 19 per cent after successive injections. Replacement apparently occurred as well as loss, as about twenty-four hours after the injection the calcium content of the blood was appreciably greater than it was one hour after the same amount was given, and in 3 experiments the effect of oxalate on blood calcium was negligible at the end of thirty hours (see Table I).

When the amount of oxalate was increased to 40 mg. per kilo, which was given subcutaneously in divided doses, and the blood was drawn one-half to one hour later, the fall of serum calcium was 2.5, 5.1, and 13 per cent in 3 experiments, but, in 2 others, it was 25 and 26 per cent. The results were not greatly different, in some experiments, with 80 mg. oxalate per kilo, as the decrease of calcium, half an hour after the injection, was 11 to 20 per cent in 4 experiments, but in 2 it was 36 and 37 per cent. The calcium content of the blood, four hours after the administration of these amounts of oxalate, failed to show any change from that previously observed, in some experiments. A distinct improvement occurred, however, in others, calcium showing a rise of 8 to 13 per cent above the previous level. On the other hand, a still further depression sometimes occurred, for in one experiment, with 40 mg. oxalate per kilo, the decrease of calcium was 25 per cent one hour after the injection and 32 per cent three and one-half hours later. Analysis of the blood within twenty-three to twenty-nine hours, after the administration of 40 mg. oxalate per kilo, indicated that the blood calcium regained its normal level in some cases and was 12 and 16 per cent below in 2 others. The changes were even more irregular after 80 mg. oxalate per kilo, the decrease of blood calcium in 2 experiments being greater on the day following than it was a few hours after the injection, and in one of these, depression of the calcium level continued as the concentration, fifty hours after oxalate was given, was less than on the previous day. In 4 other experiments, in which the fall of blood calcium half an hour after the administration of this amount of oxalate was 16 to 20 per cent, no significant change occurred in the course of about twenty-

A distinct tendency to recovery was indicated, however, by the results of the analysis of the blood obtained four hours after oxalate was injected. The decrease of blood calcium at this time, after 30 mg. oxalate per kilo, was only 6 to 13 per cent, the average being 8.4 per cent, whereas the reduction, ten minutes after this dose was given, varied between 11 to 25 per cent with an average of 18 per cent. In experiments with 40 mg. oxalate per kilo, the reduction of blood calcium at the end of two and one-half hours to five and one-half hours varied approximately between 21 and 27 per cent. With the exception of one experiment, in which the decrease at the end of five hours and forty minutes amounted to 8 per cent only, the average was about 25 per cent, representing a gain of 6 per cent over that observed six to seventeen minutes after the injection. The increase was thus 3 to 4 per cent greater after 30 mg. oxalate per kilo, during a period of about three to three and one-half hours. A further, and much greater, rise in the concentration of calcium occurred during the following period, of about twenty hours. In 2 experiments with 30 mg. oxalate per kilo, the blood calcium was only 5 and 6 per cent below normal, while in a third, restoration was complete. That the recovery was distinctly slower after 40 mg. oxalate per kilo was also shown in this case, as in one experiment the level of blood calcium was still 14 per cent below that of the control period.

When larger doses of oxalate were given intravenously, the depression of the calcium level was, of course, more pronounced than in the experiments with smaller amounts, but the relative decrease was not always proportional to the quantity injected. The loss was 8.1 mg. in one experiment one minute after the injection of 70 mg. oxalate per kilo, in another this was only 6.8 mg., though the dose of oxalate was 80 mg. per kilo, the percentile fall amounting to 66 and 62 per cent respectively. The loss was not greatly different when the dose of oxalate was still further increased. Three and five minutes after the injection of 110 and 120 mg. oxalate per kilo, the loss of calcium was 7.5

cium, before oxalate, was almost constant, being 10.0 to 10.3 mg. per 100 c.c. serum, while in one cat only it was 9.6 mg. Illustrative protocols, in brief, are given in Table III.

TABLE III

SERUM CALCIUM AFTER INTRAVENOUS INJECTIONS OF 20 MG. SODIUM OXALATE PER KILO

Cat 6, Male, Wt. 2.8 Kilo

11:00 A.M.	10 c.c. blood drawn immediately after death	7.3		

This inequality in the reduction of blood calcium, produced by the same amount of oxalate, is not easy to explain but, according to Percival and Stewart¹⁰ and to Liu,^{11, 12} the quantity of parathyroid hormone in the circulation determines the amount of diffusible calcium, and since oxalate combines with this fraction of the total calcium, the difference in the extent of depletion may thus be accounted for. A wide divergence in the effect produced was also observed when larger doses of oxalate were injected, for, ten minutes after the administration of 30 mg. per kilo, calcium was decreased 10 to 25 per cent in 7 experiments and, as in the case of the preceding experiments, the two extremes were met with, a reduction of 3 per cent only in one and 48 per cent in another. When the dose was raised to 40 mg. per kilo, the range was 25 to 49 per cent in 10 experiments, while in one case the reduction was only 12 per cent. Notwithstanding, however, the fluctuations in the calcium level observed after oxalate in these experiments, it was, nevertheless, found that the average decrease rose with the size of the dose.

In the absence of the complicating factors of the absorption of oxalate, the replacement of calcium in these experiments could be studied with greater advantage than after subcutaneous injections. There was scarcely any indication of recovery for about one and one-half hours after it was administered, as examination of the blood obtained at the end of this time, after 30 and 40 mg. per kilo, failed to show any appreciable change in the concentration of calcium from that observed when blood was drawn a few minutes after the intravenous injection of oxalate. On the contrary, a further decrease of calcium could sometimes be noticed since we found, in one experiment (5R Table IV), that the concentration fell 15 per cent below normal after ten minutes and 22 per cent fifty minutes later.

crease of calcium averaged 2.0 mg., while the relative decrease was 18 per cent. After the same amount of oxalate per kilo was given to thyroparathyroidectomized cats, the average decline was only 0.45 mg. calcium per 100 c.c. with an average of 13 per cent for the relative decrease. The fall of the calcium level was much greater when 40 mg. oxalate per kilo were given, the average decrease in normal and thyroparathyroidectomized animals being respectively 3.5 and 0.8 mg., while the relative decrease was 33 per cent in one and 17.3 per cent in the other. It may be remarked in this connection that these data do not include abnormal deviations from the above levels. The decrease of calcium after removal of the thyroids and parathyroids, in one experiment with 30 mg. oxalate per kilo, was negligible, while in another, after 40 mg. oxalate per kilo, the loss was 2.5 mg., whereas in the rest this varied between 0.7 and 1.0 mg. The loss of calcium was also much greater in normal than in thyroparathyroidectomized animals when the doses were considerably increased. After 70 to 120 mg. oxalate per kilo, injected into normal cats, the average decrease was 7.7 mg. calcium per 100 c.c. serum, and the relative decrease was 70 per cent. In thyroparathyroidectomized animals, that received 80 to 140 mg. oxalate per kilo, the absolute reduction averaged 3.5 mg. and the percentile fall was 60 per cent. Of interest also are the data presented above as showing that the difference in the decrease of calcium in normal and parathyroidectomized animals is much greater after small than after large doses, the ratios being about 4:1 and 2:1 respectively.

The duration of the effect of oxalate was also studied in cats after removal of the thyroid and parathyroids, but the observations were confined to experiments with doses of 30 and 40 mg. of sodium oxalate per kilo. The level of blood calcium, about one hour after the injection, was not greatly different from that observed ten minutes after the salt was given. In one experiment only was the difference appreciable as the decrease was 13 per cent ten minutes after oxalate and 23 per cent one hour later. The decline in the concentration of calcium at the end of four hours showed that it was only 8 per cent more in one and 9 per cent more in another, while in a third the decrease was, on the contrary, 4 per cent less than it was three hours previously. As the diminution, during the same period in another experiment amounted to 21 per cent, the earlier attempt at recovery may be regarded as exceptional. Although improvement occurred on the following day, the amounts of calcium were 0.9 to 1.3 mg. below those before oxalate, while the relative differences were 12 to 21 per cent. When the effect is compared with that produced by the same amounts of oxalate in normal cats, it becomes evident that the recovery is retarded after extirpation of the parathyroids.

DISCUSSION

The picture of the blood calcium in normal cats, before the intravenous administration of oxalate, presented a striking contrast to that observed after its injection. Whereas the concentration of calcium was practically constant or showed small differences only, before treatment, a wide range of variation occurred after oxalate, even when the same amount, in proportion to body

and 8.4 mg., the percentile reduction amounting to 73 and 79 respectively. As calcium depletion was 18, 31, and 66 per cent, after doses of 30, 40, and 70 mg. respectively, it shows that the depression increased with, but was out of proportion to, the size of the dose. This does not hold, however, in the case of still larger doses, for the average diminution of calcium after 110 and 120 mg. oxalate per kilo was about 76 per cent, which is considerably below the figure demanded if the decrease were proportional to these amounts. There is apparently a maximum dose of oxalate above which the decrease of calcium proceeds very slowly.

The blood calcium when oxalate was given after removal of the thyroid and parathyroids presented quite a different picture from that observed after it was administered to normal animals. The difference may be readily appreciated by comparing Tables IV and V, and is further emphasized in Table VI, in which the average losses of calcium in normal and in thyroparathyroidectomized cats are reported.

TABLE V

SERUM CALCIUM AFTER INTRAVENOUS INJECTIONS OF SODIUM OXALATE INTO THYROPARATHYROIDECTOMIZED CATS

As shown in Table VI, the absolute as well as the relative decrease of calcium was considerably greater in normal animals than after removal of the thyroid and parathyroids. It will be noticed that, about ten minutes after the injection of 30 mg. sodium oxalate per kilo into normal cats, the absolute de-

fore, justify the conclusion that the function of the parathyroids form an important element and may, indeed, be the principal factor in the determination of the effects of oxalate on the changes in blood calcium.

SUMMARY

1. The subcutaneous injections of oxalate produced the following changes in serum calcium: A single dose of 20 mg. per kilo was without any effect, but a progressive decrease of calcium occurred when this amount was given daily over a period of several days. A dose of 40 mg. oxalate per kilo caused a very moderate decrease of calcium within half an hour after the injection, and was much greater, about four or five times, after an interval of one hour. Signs of recovery were observed about four hours after the injection, and the normal level of calcium was regained in about twenty-four hours. When the dose was increased to 80 mg. per kilo, depletion of calcium half an hour after the injection was considerably greater than after 40 mg. doses. A moderate rise was observed four to five hours later, and although improvement was marked, in most cases, on the following day, no change or even a further decline of calcium was observed in some cases. Complete recovery occurred about two days after the injection.

2. The effects of oxalate after intravenous injections. An average decrease of 20 per cent occurred about ten minutes after 20 and 30 mg. per kilo, and a reduction of approximately 33 per cent ten to seventeen minutes after 40 mg. per kilo. A moderate amount of recovery was observed about four to five hours after the injection of 30 mg. oxalate per kilo, which was much less when 40 mg. per kilo were given. Although the rise in serum calcium was considerable after 30 and 40 mg. per kilo on the day after the injection, it was much less after the latter amount. The reduction of the absolute amount of calcium after 70 to 120 mg. oxalate per kilogram was much greater, but the relative decrease was less than after smaller doses.

3. After extirpation of the thyroid and parathyroids, the average decrease of calcium caused by the intravenous injection of oxalate, of 30 and 40 mg. per kilo, was about a fourth of that produced by the same amounts in normal animals, but the amount of reduction by large doses, the maximum of which exceeded that given to normal cats, was less than half of that produced in normal cats.

4. The results were discussed and the explanation offered that the effects on blood calcium after small, repeated doses and after large single doses, of oxalate injected subcutaneously, were due to the injury which it caused to the parathyroid, and that variation in the amount of diffusible calcium, due to different amounts of parathyroid hormone, was the main, if not the only, factor in determining the wide range of reduction of calcium in normal animals after the intravenous injection of oxalate. The small decrease of blood calcium after the administration of sodium oxalate to thyroparathyroidectomized cats was attributed to the low content of diffusible calcium.

weight, had been administered. As the changes in blood calcium, when oxalate was given after removal of the parathyroids, manifested, on the contrary, only small variations, it is evident that a close relationship existed between parathyroid function and the extent of calcium depletion produced by oxalate in normal animals. The observations of Percival and Stewart as well as those of Liu, referred to above, have shown that the amount of diffusible calcium varied with the quantity of parathyroid hormone, while Trendelenburg and Goebel¹³ and later Salvesen and Linder¹⁴ found that it was the diffusible rather than the inactive calcium which was decreased in tetania parathyreo-priva, which would explain the difference we observed, since it is this fraction which is, in all probability, acted upon by oxalate. As the hormone would be greatly reduced after extirpation of the parathyroids, a correspondingly lower decrease in calcium, produced by oxalate, should occur, as was indeed the case. This would be contradicted, however, by the large reduction of calcium, after doses of 80 to 140 mg. per kilo, which, as shown in Table VI, averaged 3.5 mg. Of interest in this connection is the suggestion of Salvesen and Linder¹⁴ that the nondiffusible is transformed into diffusible calcium, in order to maintain the equilibrium between the two forms. That the diffusible calcium determined the extent of reduction, even after large amounts of oxalate were injected, was made highly probable by the greater decrease in normal than in thyroparathyroidectomized animals.

That the changes in blood calcium after subcutaneous injections of oxalate are also related to parathyroid function is suggested by the following observations. In experiments with small doses given daily, over a period of several days, it was found that the first injection was practically without any effect. Since the same amount given intravenously produced a considerable fall of blood calcium, the difference must be due to absorption. As oxalate when given subcutaneously would enter the circulation gradually, the small quantity of blood calcium thus bound is probably replaced by the activity of the parathyroid hormone, and the normal level is thus maintained. The reduction of calcium, when the injection of the same amounts of oxalate was continued for several days, may be explained if the toxicity and cumulative effect of the latter are taken into consideration. It has been shown by Salant and Swanson,¹⁵ Gates and Meltzer,¹⁶ Gates,¹⁷ and later by Gross,³ that oxalate is of itself toxic, and Salant and Swanson pointed out, in experiments on rabbits, that its effect was also cumulative, which was corroborated by us in experiments on cats. It is highly probable, therefore, that oxalate is injurious to the parathyroids, and that their function is depressed, thus interfering with the restoration of calcium. Injury to the parathyroids might likewise be a causative agent in the slow recovery sometimes observed after larger doses of oxalate, since the increased deficiency of hormone, by the greater damage to the gland, would necessarily lessen the speed of replacement and thus delay the return of blood calcium to its normal concentration. The same mechanism would likewise account for the progressive decline in the amount of blood calcium after the injection of large doses of oxalate, namely, failure to replace the calcium bound by oxalate. The results, presented above, there-

FIVE HUNDRED AND NINETEEN VOGE BROMINE TESTS OF URINE FOR PREGNANCY*

A. M. YOUNG, M.D., CLEVELAND, OHIO

EXAMINATION of 519 specimens has shown that the Voge bromine test is far from a satisfactory test for the diagnosis or exclusion of pregnancy. Positive results were obtained in but 63 per cent of the pregnancy urines and negative results in only 84 per cent of the nonpregnancy urines.

Voge¹ in 1929 proposed a bromine test for pregnancy based on the principle which he states as follows: "In view of the fact that a connection has been established between the elaborated product of the pituitary and compounds of B-iminazolyI (histamine, histidin and tethelin), it was thought advisable to test for the presence of this substance in the urine of pregnant women." He applied Knoop's² bromine test for histamine to the urine in the following way: To 2½ c.c. of urine in a test tube add 1 c.c. of bromine water. Heat to boiling.

In a positive test the color changes to pink in an alkaline urine or brownish pink in an acid urine, the color fading rapidly. In a negative test the color remains unaltered. The bromine water is prepared by diluting one part of 2 per cent bromine water with two parts of tap water.

Voge reported the results of his test with 60 specimens, the diagnoses being established by Aschheim-Zondek tests on the same specimens of urine. As will be seen in Table I he obtained excellent results in this small series of cases. Dodds³ in 1930 and Siddal et al.⁴ in 1931 reported their results with the test. Their percentage of agreement was much lower than that of Voge as will be seen in Table I in which are tabulated the results of the three reports, as well as our results in 519 specimens.

TABLE I

CONCLUSION

Examination of 519 specimens has shown that the Voge bromine test is far from a satisfactory test for the diagnosis or exclusion of pregnancy. Positive results were obtained in but 63 per cent of the pregnancy urines and negative results in only 84 per cent of the nonpregnancy urines.

PHYTOPHARMACOLOGY OF STOMACH WASHINGS IN VARIOUS
DIGESTIVE DISORDERS AND PERNICIOUS ANEMIA*

DAVID I. MACHT, M.D., AND MOSES PAULSON, M.D., BALTIMORE, MD.

DURING the past ten years the senior author has been developing a department of pharmacology to which the name of *phytopharmacology* has been applied. In this new field a comparative study was made in regard to the effects of various drugs, poisons, and toxins on living animal preparations, on the one hand, and living plant tissues, or plant protoplasm, on the other. These studies have led to some very interesting conclusions. It was discovered that living plant protoplasm may be much more sensitive to certain poisons than living animal protoplasm; and this was found to be particularly true of poisons or toxins elaborated by animals. By the use of quantitative phytopharmacologic methods, the first experimental evidence of the presence of various toxic substances in body tissues in certain pathologic conditions was obtained. Macht and Lubin showed the presence of a menotoxin or toxic substance in the blood, saliva, milk, perspiration and other secretions of women at the time of catamenia;¹ and these findings have since been confirmed by other investigators.^{2, 3, 4} Again, for the first time, Macht and Pels have demonstrated experimentally the presence of a toxic body in the blood serum and bullae of the baffling skin disease, pemphigus.⁵ Perhaps the most interesting findings so far obtained by Macht and his collaborators have been those resulting from their studies on pernicious anemia, the first of which was published in 1926.⁶ While making a routine examination of specimens of normal and pathologic blood sera from numerous patients, the senior author found that serum from pernicious anemia cases exhibited very marked and characteristic toxicity for living seedlings of *Lupinus albus* grown in

*Received for publication, December 13, 1932.

cases makes the test of little value. The error of 13.1 per cent in the non-pregnant group makes the test valueless in the diagnosis of pregnancy."

The 519 tests reported here were done somewhat differently than originally proposed by Voge. Two tubes, in place of one, each containing 2½ c.c. of clear or filtered urine were used and to one 0.25 c.c. of bromine water was added, and to the other 0.5 c.c. of bromine water.* The test with the smaller amount of bromine was performed, since it was noted that in some pregnancy urines of low specific gravity (1.015 and less) the test with 0.5 c.c. of bromine was negative whereas with less bromine a definite pink color developed.

An analysis of the results obtained with the test using 0.25 c.c. of bromine water showed that while it increased the percentage of positive results in pregnancy urine from 54 per cent to 63 per cent it also increased the percentage of false positive results in nonpregnancy urine from 12 per cent to 16 per cent.

The quantitative feature of the test is explained by Hunter⁵ in a note on his modification of the Knoop test for histamine as follows: "The color produced is very soluble in an excess of bromine and in a dilute solution of histamine an initial excess may prevent all color development. The difficulty of adding just sufficient bromine water to slightly colored solutions has been overcome by adding a definite excess and washing out the excess with chloroform."

The simpler expedient of using two quantities of bromine also satisfies the quantitative requirements of the test.

A number of the positive results in our series were obtained in specimens from children. By deducting these tests and recalculating the percentage of false positive results, the total is 13 per cent which is similar to that obtained by Dodds whose specimens were all from women.

COMMENT

The Aschheim-Zondek and Friedman tests of urine for pregnancy are well known and their great accuracy and value have been well established by numerous workers. These biologic tests, however, requiring the use of mice or rabbits are expensive and time-consuming, and there is need for a simple chemical test for pregnancy. As reported above the Voge test is unsatisfactory for this purpose.

Von Mertz⁶ in 1928 proposed a chemical test for pregnancy on blood serum using as a test reagent phosphotungstic acid ($\text{H}_3\text{PO}_4 + 12\text{WO}_3 + 12\text{H}_2\text{O}$). He obtained 94.9 per cent agreement in 650 cases. Unfortunately this work has not been sufficiently confirmed and Kilduffe and Steinig⁷ have recently (1932) reported unsatisfactory results with it. They obtained a very low percentage of positive results (10.4 per cent) in pregnancy and approximately an equal number of positive results with nonpregnancy cases.

It still remains a problem to detect by a simple chemical means some substance in the urine or blood characteristic of the pregnancy state.

*The bromine water was prepared as follows: A stock solution of bromine water was made by placing in a glass stoppered bottle 6 c.c. of bromine (under a hood) and 300 c.c. of distilled water. After shaking for about forty-five minutes, a few cubic centimeters of the bromine remained undissolved and the supernatant solution was decanted. The stock solution therefore was about 1 to 1½ per cent of bromine. The stock solution diluted further with two parts of tap water constituted the test bromine water. The test bromine water was found to lose strength quite rapidly and was not used for more than one week after its preparation.

a dark incubator and kept at a temperature of 21° C. The increment in length of the seedlings obtained with stomach washings was then compared with the increase in length of the normal controls and expressed as the *phyto-toxic index*.

Complete details in regard to the technic of the phytopharmacologic test have been given in previous publications and need no repetition in this place. It may be well, however, to state emphatically that, for careful performance of the phytopharmacologic test, a great deal of training is required not only in ordinary zoöphysiologic and zoöpharmacologic methods but also in the laboratory methods pertaining to plant physiology and botany. A beginner expecting to succeed in such work on the first attempt will more than likely be disappointed. Indeed, he may not even be able to germinate the seeds, much less to secure uniform seedlings suitable for testing. The seeds employed in the present work were those of the large variety of *Lupinus albus*. These seeds must not be too old or worm-eaten and should be soaked for twenty-four hours in tap water to insure their complete swelling before being planted in the proper germinating medium. Finely ground sphagnum moss is the most suitable medium for germinating seeds. It is of vital importance, however, that such moss should be free from acid matter and contain just the proper amount of moisture, namely, 75 to 80 per cent its weight. The sphagnum moss should be thoroughly aerated and not closely packed; and, after planting, the seeds should be set aside in the dark and kept at a temperature no higher than 22° C. When a higher temperature is employed, growth may be so greatly stimulated as to mask small differences produced by inhibitory substances in the various solutions. For the performance of the test, the seedlings should have roots measuring from 30 to 40 mm. in length. Rows of eight, or ten seedlings should be employed for control solutions and for each of the solutions to be tested. To insure greater accuracy it is well to select seedlings of as nearly the same length as possible for corresponding tubes in each row.

RESULTS

The total number of cases studied was 125. The average phytotoxic index obtained from stomach washings of 100 patients, either normal or exhibiting various gastrointestinal disorders without pernicious anemia, was found to be 86 per cent. The lowest reading in these cases was 75 per cent. Table I gives a detailed analysis of the first 59 of these cases. Here are set forth the age, sex, and color of the patient, social status, the amount of free acid, the total acidity and Wassermann findings, the clinical diagnosis or impression of each case, the x-ray findings and, finally, the phytotoxic indices, obtained independently in the pharmacologic laboratory and with no previous knowledge of the history and physical findings of the various cases. It will be noted that of the 59 cases 11 gave phytotoxic indices ranging from 76 to 80 per cent; 31 gave phytotoxic indices between 80 and 90 per cent; and 15 cases gave phytotoxic indices between 90 and 100 per cent. Two cases gave a reading over 100 per cent, the highest being 101 per cent. The phytotoxic indices in these cases and of all the stomach washings which were

plant physiologic solution. The toxin was not menotoxin because it was present in male patients suffering from pernicious anemia, but it was not present in other blood diseases such as secondary anemia, carcinoma, leucemia, etc. The phytopharmacologic method therefore not only furnished a contribution to the etiology of Addison's or primary anemia but also offered a method of establishing a differential diagnosis between pernicious anemia and other anemias simulating it.⁷ Later investigations elaborating the phytopharmacologic method of study furthermore offered a convenient means of evaluating various methods of therapeutic procedure employed in the treatment of pernicious anemia.⁸ The findings obtained by means of this method of study in various diseases have been confirmed by numerous investigators, notably by Tschérkes,⁹ Tschérkes and Goldstein,¹⁰ Tschérkes and Mangubi,¹¹ Etinger and Artinov,¹² Stern,¹³ Herz and Weichbrodt,¹⁴ and Macht and Pels.¹⁵

More recently, Macht has demonstrated the presence of the pernicious anemia toxin not only in the blood but also in the spinal fluid of such patients.¹⁶ A comparative phytopharmacologic study of spinal fluids from various conditions had led to the discovery of a definite toxicity in the spinal fluid of patients suffering from true pernicious anemia. This method is already being employed by some physicians for differential diagnosis of neurologic signs and symptoms produced by pernicious anemia, on the one hand, and other conditions simulating it, on the other. These findings suggested the undertaking of the present investigation. It was deemed worth while to inquire whether the stomach washings obtained from various normal and pathologic conditions showed any difference in toxicity when examined by the new phytopharmacologic method.

METHOD

After various preliminary experiments the following method was adopted. The empty stomach of the patient was washed out with 100 c.c. of distilled water. This was done by introducing water through a clean stomach tube, which had been previously sterilized and washed free from any trace of antiseptic. The washings thus obtained were tested for their hydrogen ion concentration and then submitted for special examination to the pharmacologic laboratory. The phytopharmacologic method employed was the same as that used in the study of spinal fluid and blood.¹⁷ While a one per cent solution of the blood serum was employed in these experiments, a 2 per cent solution of the stomach washings was made because of the more dilute condition of the specimens at the outset. Such a 2 per cent solution was made in a plant physiologic saline consisting of equal parts of Shive solution and distilled water.¹⁸ Healthy young seedlings of *Lupinus albus* were placed in hard glass tubes containing such a liquid and the growth of their straight and well-defined single roots in normal physiologic saline was compared with the growth of roots of similar seedlings from the same crop and of approximately the same initial length, immersed in the physiologic solution of the stomach washing. The length of the roots was measured at the beginning of the experiment and twenty-four hours after the preparations had been placed in

studied bore no relation whatever to the hydrogen ion concentration of the solutions used because a 2 per cent solution of such gastric washings in plant physiologic saline, which normally gave a reading of P_H 4.8 to P_H 5.0, was too small to change the hydrogen ion concentration to a degree sufficient to affect the growth of seedlings. The hydrogen ion concentrations of the solutions were studied by both colorimetric and potentiometric methods (Table I).

The phytotoxic indices of the cases discussed above are of interest both in regard to positive and to negative findings. Thus, for instance, it was very interesting to find that the stomach washings from several cases of carcinoma ventriculi showed no difference in toxicity as compared with those of other normal or functional gastric conditions. The most important findings, however, were made in connection with the comparative study of a series of true or essential achylas, on the one hand, and the achylas of pernicious anemia, on the other. Table II exhibits the results obtained. A total of eight cases

of essential or true achylia was studied. These cases were investigated clinically and all proved to be of a severe type which did not respond with secretion of hydrochloric acid even after injections of histamine. In all these cases, morphologic and microscopic blood examination excluded pernicious anemia. It will be seen that the average phytotoxic reading given by the eight cases was 85 per cent, which was the same as the figure obtained in the series of 100 cases mentioned above. On the other hand, nine cases of pernicious anemia with complete achylia, studied by the authors, yielded very definite and different results. These cases were diagnosed as pernicious anemia on the basis of complete clinical, physical, and laboratory tests as well as on the basis of phytopharmacologic examination of the blood specimens. The average phytotoxic index given by the stomach washings from these nine cases was 59 per cent, a figure far below that obtained in other gastrointestinal conditions (Table II).

DISCUSSION

The findings described above in connection with the study of different samples of stomach washings from various clinical conditions are obviously of manifold interest to the physician. In the first place, the toxic reaction of the specimens obtained from cases of primary anemia promises to be of value

in the differential diagnosis of the achylia characteristic of that disease from other forms of achylia. In the second place, the peculiar toxic reaction produced by stomach washings from pernicious anemia cases is a property to be borne in mind in theoretical discussions in regard to the etiology of that disease. In the third place, the present findings have an added interest in connection with the treatment of pernicious anemia since the relative toxicity of stomach washings from a given patient, before and after instituting any special method of therapy, will furnish an index as to its efficiency.

Problems of gastric acidity have been brought into renewed prominence by the current intensive studies of pernicious anemia and of cancer of the stomach. As is well known, both these diseases are characterized by anacidity or achylia. Moreover, Pollard and Bloomfield¹⁹ have recently called attention to the surprising number of persons presenting an inexplicable anacidity of the stomach. Consideration of the different types of achylia or anacidity should make any new method of differentiating between the various forms especially welcome. Thus, the recent introduction of histamine as a potent stimulus to the secretion of free acid by the gastric mucosa has been of considerable aid in classifying various forms of anacidity. The phytotoxic test promises to be another such aid because phytopharmacologic examination of stomach washings indicates a distinct and marked difference between essential achylia, resistant to histamine injections, and that of pernicious anemia. What light these findings may shed on the etiology of primary anemia we cannot say at present but the experimental data are none the less valuable. In this connection it may be well also to bear in mind the more or less successful results obtained in the treatment of pernicious anemia with desiccated stomach mucosa. It is hoped that the present report will stimulate further investigation along phytopharmacologic lines.

SUMMARY

1. A phytopharmacologic examination, according to a standardized technique, was made of stomach washings obtained from 125 clinical cases, who had received no food for at least twelve hours.

2. The average phytotoxic index of one hundred patients not suffering from achylia was found to be 6 per cent.

3. A few cases of gastric carcinoma showed no difference in toxicity from other clinical conditions of a benign or functional character.

4. The average phytotoxic index for nine cases of definite pernicious anemia with no free hydrochloric acid was 59 per cent.

5. The average phytotoxic index of eight cases of essential achylia, which failed to respond with secretion to injections of histamine, was found to be 85 per cent.

6. The difference in phytotoxic effects between stomach washings obtained from cases of pernicious anemia, on the one hand, and essential achylia, on the other, promises to be of clinical value in differentiation of the two conditions and warrants further studies along the lines described above.

The spectroscopic studies of the blood are of interest and significance, and are here given in detail. All blood samples were obtained from the median basilic vein. The first one, taken before treatment, had a distinct chocolate color. One part of this sample was diluted with 49 parts of distilled water, resulting in a reddish brown solution. This was examined spectroscopically, and showed the characteristic absorption bands of neutral methemoglobin between the C and D lines. A sample of blood taken twenty-four hours later, diluted as above, and examined spectroscopically, did not show any evidence of methemoglobinemia, but gave the characteristic absorption bands of oxyhemoglobin. (Plate I.)

Since the patient had been handling two distinctly different anilin products, parabromanilin, and parabromorthosulphanilic acid, animal experiments were undertaken to determine which of the two, or whether both of the substances were responsible for the poisoning of the patient.

Plate I.—Showing spectrograms of blood of patient poisoned by contact with an anilin dye before and after the intravenous injection of methylene blue, as follows:

1. Blood of patient immediately before injection of methylene blue, showing pronounced neutral methemoglobin band.
2. Methemoglobin control.
3. Patient's blood one hour after injection of methylene blue showing normal oxyhemoglobin band.
4. Oxyhemoglobin of normal blood. Control.

Three rabbits were used. Rabbit No. 1 was a control, and received an injection of the 1 per cent methylene blue. Rabbit No. 2 was treated with an application of parabromanilin, in the form of a paste which was rubbed thoroughly into the skin. Rabbit No. 3 was treated in a similar manner with parabromorthosulphanilic acid. Rabbits No. 2 and 3 were later given injections of methylene blue.

Animal No. 2, treated with parabromanilin, became profoundly ill. Spectroscopic examination of the blood showed a marked neutral methemoglobinemia, which cleared up very rapidly after the injection of methylene blue.

Animal No. 3 showed no evidence of poisoning from the application of parabromorthosulphanilic acid, aside from a slight irritation at the site of

METHYLENE BLUE AS AN ANTIDOTE FOR ANILIN DYE POISONING^{*}

CASE REPORT WITH CONFIRMATORY EXPERIMENTAL STUDY

JOHN R. WILLIAMS, M.D., AND FRANK E. CHALLIS, ROCHESTER, N. Y.

THE recent press and technical journal notices regarding the use of methylene blue in the treatment of cyanide and carbon monoxide poisoning influenced the writers to try this procedure in a case of anilin dye poisoning, the details of which appear in the following report.

A male university student, aged twenty-three, while engaged in experimental work in a chemical laboratory, handled with his bare hands large quantities of para bromanilin and parabromorthosulphanilic acid. Intimate contact with the dye began about ten o'clock in the morning. In one portion of the experiment, while evaporating the material over an open flame, he inhaled the fumes for about an hour. At the end of this time it was noticed that his skin was becoming discolored. About twelve-thirty he left the laboratory and drove to his home. On the way he experienced a feeling of dizziness which gradually changed to severe headache. About 3 P.M. stupor developed. When seen at 4 P.M. the patient was semicomatose, had a severe headache, and the skin showed a discoloration suggesting an intense cyanosis. The color approximated a mauve lavender.

At this time the nature of the poisoning agent was not definitely known, and because of the grave condition of the patient, it was decided to remove him to the hospital and to try experimentally the methylene blue treatment as used by Geiger.

The patient was admitted to the Highland Hospital about 4 P.M. He was given at once, intravenously, 600 c.c. of 18 per cent glucose solution, plus 100 c.c. of 1 per cent methylene blue. Soon after the injection of this mixture was begun, the skin pigmentation began to disappear. In one hour the lips and nails became a normal pink color. The headache rapidly subsided. About 11 P.M. the patient was greatly improved and without headache. The skin, so far as could be observed, was normal in color.

Before instituting any treatment, and at irregular intervals thereafter, specimens of blood were taken for spectroscopic and other examinations. These disclosed that there was no disturbance in hemoglobin, red cell, white cell, or differential count. Blood sugar and blood nitrogen were also normal. The urine was normal both chemically and microscopically. A complete physical examination was made, which, except for the discoloration of the skin, was without significance. The pyrotannic test of the first sample of blood for carbon monoxide was normal.

^{*}From the Highland Hospital.

Rabbit No. 1. Male, weight 1725 grams, given 1 cubic centimeter of the methylene blue solution. Samples of blood were taken before, and at one hour and four hours after injection. Spectroscopic examination showed oxyhemoglobin bands, but no methemoglobin. (See Plate II, Spectra 1 and 2.)

Rabbit No. 2. Male, weight 1880 grams, parabromanilin paste poured on animal's back and rubbed in well with wooden spatula. At the end of 30 minutes the animal was in distress, having an accelerated heartbeat, and quickened breathing. At the end of the first hour, the rabbit was very ill, and showed evident collapse. A sample of blood taken and diluted with 49 parts of distilled water gave a reddish brown solution, which on spectroscopic examination showed a definite absorption band of methemoglobin. (See Plate II, Spectrum 3.)

At five hours the rabbit was much worse, weaker, unable to sit up in normal position, and leaning against the side of the cage for support. Breathing rapid. Marked cyanosis of

Plate III.—Showing spectrograms of control tests as follows:

1. Mercury arc.
2. Rabbit's blood before injection of methylene blue, normal oxyhemoglobin.
3. Rabbit's blood one hour after injection of methylene blue in twice the proportionate amount given to the patient, showing normal oxyhemoglobin.
4. Test tube mixture of normal blood and methylene blue. This seems to be a composite of the bands of oxyhemoglobin and methylene blue.
5. Dilute watery solution methylene blue.
6. Methemoglobin control.

ears. Second sample of blood taken, diluted as before, and examined spectroscopically. Blood chocolate color. Watery solution brown. Neutral methemoglobin bands very marked.

At six hours, rabbit very ill, and with no apparent improvement. Methemoglobin bands very strong. Rabbit given 1 cubic centimeter of methylene blue intravenously. (See Plate II, Spectrum 4.)

At seven hours, rabbit much improved, almost normal. Blood taken as before, and diluted with water. Blood normal in color, gives bright red solution. Spectroscopic examination shows normal oxyhemoglobin bands, no methemoglobin. (See Plate II, Spectrum 5.)

During this entire experiment the parabromanilin paste was not removed from the animal's back except as the rabbit itself licked and rubbed it away. After twenty-four

application. Spectroscopic examination of the blood showed the absorption bands of oxyhemoglobin, but no methemoglobin. (Plate II.)

The materials and apparatus used for this test, and details of the experiment are as follows:

1. Parabromanilin, 5 grams. Fifty per cent solution of ethyl alcohol and distilled water sufficient to make a thin paste.
2. Parabromorthosulphanilic acid, 5 grams. Fifty per cent solution of ethyl alcohol and distilled water sufficient to make a thin paste.
3. Methylene blue (Merck) medicinal, 1 per cent watery solution.
4. A Bausch and Lomb Universal Spectrophotometer, with camera attachment.

Plate II.—Showing spectrograms of bloods removed from experimental animals as follows:

1. Blood of Rabbit No. 1 before injection of methylene blue, showing the bands of oxyhemoglobin.
2. Blood of Rabbit No. 1 one hour after the injection of methylene blue, the oxyhemoglobin band being unaltered.
3. Blood of Rabbit No. 2 one hour after the application of parabromanilin to the skin, showing neutral methemoglobin.
4. Blood of Rabbit No. 2 at six hours, still showing a pronounced methemoglobin band.
5. Blood of Rabbit No. 2 one hour after injection of methylene blue. Methemoglobin band has been replaced by that of oxyhemoglobin.
6. Blood of Rabbit No. 2 after twenty-four hours, still showing oxyhemoglobin.
7. Blood of Rabbit No. 3 one hour after cutaneous application of parabromorthosulphanilic acid. Oxyhemoglobin present.
- 8 and 9. Same blood four and five hours later. Blood apparently not affected by the treatment.
10. Mercury arc.

Sahlin's work in 1930 and 1931, as cited by Hanzlik.² Geiger was apparently the first to make clinical application of the procedure. For a statement as to the history and priority of the method, the reader is referred to Hanzlik's communication.

Brooks³ found that methylene blue shortened the time of recovery from hydrocyanic acid poisoning to about one-third, and that from carbon monoxide to about one-half that of untreated animals. The results suggest that there is an activation of oxygen by methylene blue which manifests itself when aerobic oxidation is interfered with, and that it could be used advantageously in cases of hydrocyanic acid or carbon monoxide poisoning.

Geiger⁴ reports three cases of cyanide poisoning ending in death, where the usual restorative methods failed. In a fourth and similar case, the patient was saved by the intravenous use of methylene blue, the treatment being suggested in this case by Doctors P. J. Hanzlik and C. D. Leake, of the University of California Medical School. Geiger later reports two cases of carbon monoxide poisoning treated with favorable results by the use of methylene blue.

A fourth report is by Nass,⁵ who employed methylene blue in conjunction with carbon dioxide, oxygen inhalations, and other remedies in a case of illuminating gas poisoning, with successful outcome.

Since the preparation of this manuscript several communications have appeared in the literature, reporting the successful use of methylene blue in carbon monoxide poisoning. Haggard and Greenberg⁶ sound a note of warning against the employment of methylene blue as an antidote. They assert that its use is fraught with danger, and support by chemical experiment Wendel's contention that methylene blue forms methemoglobin in the blood.

Our clinical observations on this point do not sustain Haggard and Greenberg's conclusion. This investigation throws no light on the mechanism of the methylene blue action in the blood. That in itself is an interesting problem which awaits solution.

NOTE: The writers wish to acknowledge with sincere thanks the assistance of the technical research division of the Bausch and Lomb Optical Company.

hours a fourth sample of blood was taken, and proved to be normal both in appearance and spectroscopic examination. (See Plate II, Spectrum 6.)

Rabbit No. 3. Male, weight 1460 grams, parabromorthosulphanilic acid rubbed into animal's skin, and blood taken at one, four, and five hours after application. Rabbit remained normal, and spectroscopic examination of blood showed no evidence of methemoglobinemia. (See Plate II, Spectra 7, 8, and 9.)

Since it has been reported by Wendel¹ that methylene blue injected intravenously produces methemoglobinemia, a male rabbit weighing 1650 grams was given 3.5 cubic centimeters of 1 per cent watery solution of methylene blue. Before the injection was completed, the bluish discoloration of the sclerae of the eyes began to appear. After fifteen minutes the sclerae were definitely blue, as was also the mucous membrane lining of the eyelids and mouth. At the end of one hour 0.5 cubic centimeters of blood was withdrawn, and diluted with 49.5 cubic centimeters of distilled water. This was examined spectroscopically. There was a marked shortening of the red end of the spectrum, but no evidence of the methemoglobin band. (See Plate III, Spectrum 2.) Blood was withdrawn again at the end of four hours, and examined with similar results. (See Plate III, Spectrum 3.)

For purposes of comparison, Plate III contains absorption spectra of oxyhemoglobin, neutral methemoglobin, and fresh blood mixed with methylene blue. (See Plate III, Spectra 1, 5, and 4.)

SUMMARY AND CONCLUSIONS

A case is described of anilin dye poisoning in a human being who had been handling parabromanilin and parabromorthosulphanilic acid, absorption presumably taking place from the skin. Intense signs and symptoms of pigmentation of the skin, headache, stupor, nausea, and vomiting rapidly supervened. These were promptly relieved by the intravenous injection of 1 per cent solution of methylene blue. Chemical, microscopic, colorimetric, and spectroscopic examinations were made of the bloods of both patient and experimental animals to determine the effect of cutaneous applications of the materials in question. It was definitely shown by spectroscopic studies of the blood that the poisoning in this case was due to parabromanilin, and that the parabromorthosulphanilic acid was nontoxic when applied to the skin.

The animal experiments indicated that methylene blue injected intravenously into a rabbit in approximately twice the strength of that given to the patient did not affect the absorption spectrum of normal blood, but if methylene blue be mixed with normal blood in vitro, the spectrum from such a mixture seems to be a composite of the spectra of methylene blue and normal blood. (See Plate III, Spectrum 4.)

A search of the literature fails to reveal a case of anilin dye poisoning resulting in methemoglobinemia in which the methemoglobin spectrum was changed to that of oxyhemoglobin with prompt clearing up of toxic signs and symptoms following the injection of methylene blue.

A brief review of the literature as to the use of methylene blue as an antidote is pertinent. The first to employ it thus was Sahlin of Lund, in 1926, who administered it in a case of cyanide poisoning, Eddy confirming

blood cells per c.mm. Fig. 1 shows that 94 per cent of the cases ranged between 4 and 5.6 million red blood cells per c.mm., while 6 per cent of the cases were outside of this range. Thirty-one boys had counts of more than 5 million red blood cells per c.mm., and 4 had counts less than 4 million red blood cells per c.mm. The lowest count was 3.28 million red blood cells per c.mm., and the highest count was 5.87 million red blood cells per c.mm.

Fig. 1.—Distribution of red blood cell count in 100 boys between ages of twelve and seventeen years.

Fig. 2.—Percentage distribution of hemoglobin of 100 boys between the ages of twelve and seventeen years.

HEMOGLOBIN CONTENT

The inaccurate methods for the estimation of the hemoglobin content cannot be stressed too often. In a recent article¹⁰ the fallacy of individual estimations was also pointed out. Any hemoglobinometer may be employed as long as it is calibrated in grams of hemoglobin per 100 c.c. of blood. From this scale the percentage content of hemoglobin can be easily computed. Inasmuch

A STUDY OF THE RED BLOOD CELL COUNT AND HEMOGLOBIN IN THE ADOLESCENT MALE*

S. MILTON GOLDHAMER, M.D., AND AGNES I. FRITZELL, B.S.
ANN ARBOR, MICH.

THE necessity for establishing the normal red blood cell count and hemoglobin standard of the peripheral blood for the various age groups has become evident with the growing appreciation of the influence of various factors on the cell concentration in the circulating blood. Many of the standards which had been accepted were made without the proper critical data as to their source or accuracy. Accurate observations by Haden,¹ Rud,² Gram and Norgaard,³ Bing,⁴ Williamson,⁵ Komocki,⁶ Osgood,⁷ Wintrobe⁸ and others have been published, based on blood determinations carried out with painstaking technic in large series of individuals. As a result of their investigations, normals have been established for the various adult age groups. To these we wish to add the results obtained in a series of 100 boys in the adolescent stage.

The subjects of our study were healthy male students between the ages of twelve and seventeen years. From the data collected from various other studies, we have no reason to assume that any organic disease was present. All subjects were American born and the majority resided in the Great Lakes region all their lives.

The examinations were done in the fall of the year and throughout the entire day so that the averages eliminate diurnal variations.

The specimens of blood were obtained from punctures of the lobe of the ear. The first drop was discarded, the succeeding drops flowed freely so that no squeezing was necessary. The red blood cell counts were made on a Neubauer-Levy counting chamber (new ruling, U. S. Bureau of Standards). The pipettes used were checked by the U. S. Bureau of Standards. The hemoglobin was calculated in a Sahli hemoglobinometer in the usual manner with N/10 hydrochloric acid for one minute, diluted with distilled water, and compared with a colored rod standard. In compiling the results to be discussed, the Sahli hemoglobinometer in which 14 gm. of hemoglobin were equivalent to 100 per cent, was used because of its convenience. The instruments were calibrated and checked in accordance with the Van Slyke gas method⁹ for the estimation of hemoglobin.

RED BLOOD CELL COUNTS

As far as can be determined no large series of cases have been reported concerning the average red cell count in the adolescent stage. Our average in 100 boys between the ages of twelve and seventeen years was 4.71 million red

2. The average hemoglobin estimation is 11.55 gm. per 100 c.c. of blood or 82.57 per cent, the range being 9.80 gm. (70 per cent) and 13.58 gm. (97 per cent) per 100 c.c. of blood.

3. The average hemoglobin coefficient for the 100 cases is 12.35 gm. per 100 c.c. of blood.

4. The average color index for adolescent males is 0.87, the lowest index is 0.60 and the highest color index is 1.27.

5. If the hemoglobin coefficient be expressed in percentage rather than grams, it assumes approximately the same figure as the color index.

as the hemoglobin varies with sex, age, time of day, altitude, climate, and race, the necessity for definite standards for the various age groups is indicated.

In the 100 cases herein reported, the average hemoglobin estimation was 11.55 gm. per 100 c.c. of blood or 82.5 per cent (Sahli). The lowest value was 9.80 gm. or 70 per cent (Sahli) and the highest value 13.58 grams or 97 per cent (Sahli). Of all the estimations, 88 per cent were between the range of 75 and 95 per cent (Sahli) or 10.50 to 13.30 gm.; 9 per cent of the cases were less, and 3 per cent of the cases were more than this (Fig. 2). The average hemoglobin content of each red cell was 26^{-12} gm., which is slightly less than the value for adult males as computed by Osgood.⁷

INDICES

The color index refers to the amount of hemoglobin in the average cell, expressing the amount in proportion to the normal. Table I contains the figures from which the various indices have been computed. The average uncorrected

Fig. 3.—Color index distribution in 100 boys between the ages of twelve and seventeen years.

color index for the 100 cases is 0.87. The lowest index is 0.60 and the highest 1.27. In Fig. 3 it is noted that 83 per cent of the cases had a color index within the range of 0.80 to 1.15. Sixteen per cent of the cases had a lower color index and 1 per cent had a higher color index.

Curiously enough, if the hemoglobin coefficient be expressed as the percentage rather than the grams of hemoglobin per 5.0 million red blood cells, it has approximately the same figure as the color index. In computing the hemoglobin coefficient, it is noted that the average is 12.35 gm. per 100 c.c. which is a slightly higher value than the hemoglobin average. However, neither of these figures approaches the accepted standard for adults of 14 to 16 gm., which is recognized by the majority of investigators.

CONCLUSIONS

1. The average red blood cell count in males between the ages of twelve to seventeen years is 4.718 million per c.mm., the range being 3.28 to 5.87 million red blood cells per c.mm.

rate for lead had been increased by the lead injections, but the effects were irregular. Millet¹² was unable to find evidence that the administration of colloidal lead orthophosphate altered the rate of lead excretion in the urine of patients. Newman, on the other hand, found a definite response in the horse,⁸ and in patients,¹³ after intravenous administration of colloidal lead orthophosphate, although the increase in the urinary lead concentration was small, and slow to make its appearance, as compared to the results obtained when colloidal lead had been injected.^{8, 14}

We have studied the activity of certain insoluble particulate lead preparations in animals by methods similar to those previously employed in the study of soluble lead salts,¹⁵ and tetraethyl lead.¹⁶ We have made some observations on patients who have been treated for inoperable cancer with colloidal lead preparations. The animal experiments were designed to determine the character of the distribution of lead in the tissues, and the rate of its excretion not only immediately following injection, but also over subsequent periods during which the lead might be expected to migrate in the body.

EXPERIMENTAL METHODS

Five preparations were employed for intravenous administration.

1. A suspension of finely divided crystals of tertiary lead phosphate prepared by adding 1.5 per cent Na_3PO_4 to 0.5 per cent PbCl_2 . The mixture was filtered at once, the precipitate was thoroughly washed on the filter paper but not dried, resuspended in distilled water, and used immediately.
2. A suspension of crystals of the secondary lead phosphate prepared in similar fashion, by using the secondary sodium phosphate as the precipitant.
3. Colloidal lead orthophosphate stabilized with gelatin prepared by the method described by Bischoff and Blatherwick.¹¹
4. Colloidal lead orthophosphate procured from the Crookes Laboratories.
5. Colloidal lead from the same source.

The suspensions of crystalline phosphates were used to determine the influence of relatively large particles on the distribution of lead in animals, and to eliminate any uncertainty as to the chemical nature of the material injected. They were somewhat unsatisfactory as materials for intravenous injection, because of their tendency to block the syringe. Thus the amounts injected can only be estimated approximately. A small amount of blood was allowed to flow back into the syringe and after vigorous agitation of the contents of the syringe, the material was slowly injected. Death from embolism occurred in a few instances, but when the injection was carried out slowly the animals showed no ill-effects from any dosage employed. No attempt was made to determine the size of the particles of these suspensions.

Healthy full-grown rabbits were employed as experimental animals. Except for those that died as a result of the injection, they were sacrificed for analysis at suitable times, by bleeding from the heart under light ether anesthesia. Some of them were kept in metabolism cages from the time of injection until they were sacrificed, to follow their lead excretion. When this was done parallel observations were made on control animals. In other instances a control

THE BEHAVIOR OF LEAD IN THE ANIMAL ORGANISM*

III. COLLOIDAL LEAD COMPOUNDS

ROBERT A. KEHOE, M.D., AND FREDERICK THAMANN, CH.E., CINCINNATI, OHIO

INTRODUCTION

THE use of colloidal lead compounds in the treatment of malignant neoplasms has introduced a new factor into the problem of the physiologic behavior of lead. It may not be assumed that particulate lead compounds, injected intravenously, act in the same manner as those which are absorbed through the alimentary tract and the respiratory membranes. Thus, it is not surprising that some of the observations which have been made, following the administration of colloidal lead compounds, are not in harmony with previous experimental findings.

A review of the literature discloses certain facts upon which investigators are in agreement. Shortly after the injection of colloidal lead preparations the largest amounts of lead are found in the spleen and liver.^{1, 2, 3, 4, 5, 6, 7} Frequently the lungs contain large amounts of lead. At this time the skeleton shows relatively low concentrations, while the kidneys, heart muscle, somatic muscle, brain, testicles and intestinal tract (without contents) show variable amounts. The blood stream loses its lead at a rapid rate after an injection. Bischoff⁴ and his associates have described experiments in which virtually all the lead given as tri-lead orthophosphate was removed from the blood in two hours. Newman's⁸ observations on horses showed that about 90 per cent of colloidal tri-lead orthophosphate disappeared from the blood in the first hour, while at the end of the second hour the blood was practically free of lead. In the case of colloidal lead, the removal from the blood stream was not so rapid, nor so complete, considerable amounts remaining in the blood sixty-six hours after the injection. Both chemical and histologic evidences point to the initial distribution of the colloidal compounds in the reticuloendothelial system,^{6, 9, 10} while according to Henriques and Okkels⁹ the administration of soluble salts promotes a contrasting deposition of lead in parenchymal cells of the liver and kidney.

The ultimate fate of the colloidal lead preparations in the tissues has not been studied adequately. Apparently, the importance of time as a factor in the dynamic processes of redistribution and excretion, has not been appreciated. Bischoff and Blatherwick¹¹ have mentioned fragmentary observations as evidence that injected lead orthophosphate induces an increased lead excretion. Todd³ reports the study of the lead excretion of a patient treated with lead selenide. One would conclude from his results that the excretory

period of excretion preceded the lead injection. Other animals kept for longer periods of time after injection, were introduced into the metabolism cages for a short time just before they were sacrificed. In this way information as to the magnitude of lead excretion at long intervals after treatment was provided.

The care of the animals, the excretory studies, the preparation of animal tissues, and the analytical procedures were carried out in the manner described in previous articles.^{16, 17}

The observations on patients were made with the assistance of L. J. Schradin. The urine and feces were collected in containers provided by the laboratory. Precaution was taken against contamination of these samples from external sources. Tissues obtained at necropsy were washed in distilled water while fresh and stored in chemically clean jars.

RESULTS

We have given elsewhere the characteristic distribution of lead in the tissues of rabbits a long time after intravenous administration of lead salts.¹⁵ Examples have appeared in earlier articles, illustrating the changes in the distribution¹⁵ and excretion¹⁶ of lead, which take place with the lapse of time following the intravenous injection of soluble lead salts into rabbits. The more complete data given in this paper will permit detailed comparison of the behavior of soluble lead salts with that of colloidal compounds. Table I shows the results of the analyses of the tissues of twenty-four rabbits that had received lead chloride intravenously. These animals died or were killed after various periods of time following the lead injections. Certain tissues were not analyzed separately. Rather, the attempt was made to select those organs which gave the greatest promise of information as to the distribution of lead. The mixed tissues which, for one reason or another, were not separated into individual samples, were grouped as one marked "remainder," or were discarded. The skin, ears, and feet were usually discarded because of the possibility of their external contamination, the ears as the sites of original injection being particularly under suspicion. In the case of several animals that were employed for excretory studies, there was no such question with reference to the ears because of the time interval between injection and death. Furthermore, the skin of these animals had been carefully cleansed at the beginning of the excretory observations, and again at the death of the animal. Such animals were analyzed in their entirety.

To clarify matters, the data are expressed in three forms. The upper section of the table shows the actual quantities of lead found by analysis; the middle section gives the calculated concentration in milligrams per one hundred grams of the tissue; the lower section relates the concentration in any one tissue to the concentration in the combined mass of tissue analyzed. This demonstrates the selective nature of the localization, and allows the analytical results in one animal to be compared with those in another regardless of the absolute amounts of lead present in the tissues.

Within a few minutes to two hours after intravenous injection of lead chloride, practically all the tissues examined showed the presence of lead. Un-

*Skin and/or mixed tissues ("Remainder") discarded.

doubtedly some of this lead was in the residual blood of these tissues, and since the blood was high in lead at this time, this factor is important. However, in some organs the concentration of lead was higher than would be expected from their blood content, while the reverse was true in others. In general the kidneys, liver, spleen, and the blood were especially high in their lead content, though there was a considerable variability in the relative positions of these solid organs. Muscle tissue was uniformly low in lead, and, with one exception, the bones. (The exception [Rabbit 252] is the result of the injection of 6 mg. of lead a week before the final injection.) The amounts in the bones are somewhat higher than would be expected immediately after injection. No doubt the vascular bone marrow was responsible for a certain quantity, but the additional factor of lead present before the experimental injection may not be ignored. We have found that the lead in normal, untreated rabbits varies in amounts from 0.29 mg. to 2.60 mg., as shown in Table II and Table III. The chief influence of such normal lead in these experiments is to magnify the lead content of the skeletal tissues.

The only significant difference in the distribution of lead sixteen hours after injection is seen in the result obtained on the blood of Rabbit 237, which showed only a trace of lead. The data of these experiments are not adequate to show the time at which the greater proportion of injected lead disappears

from the blood stream. From other experiments in which only a few tissues were analyzed, it is apparent that from sixteen to seventy-two hours are required to accomplish the result.

Gradual changes in distribution occur between the first and fourteenth days. After that time no obvious evidences of change are found in the analytical results. There is a gradual diminution in the gross amount of lead in the tissues, without any striking shift from one tissue to another. There is a considerable variability among the animals, but the trend is fairly uniform. The bones have absorbed their maximal absolute amounts by the end of two weeks. From this time on, the concentration of lead in the bones does not increase appreciably, either actually or in relation to the other tissues. The spleen apparently loses the greater portion of its lead during the initial two weeks, for large amounts are not found in the spleen of any animal after that time. The liver and the kidneys usually show relatively large amounts of lead. Fatty tissue, striated muscle and intestinal tract (without contents) contain small amounts with considerable regularity. Lead was found in the skin in every analysis, and in amounts which could not be attributed to external contamination. The analysis of the central nervous system did not yield lead regularly. The amounts were small in every instance except one.

Nearly 80 per cent of the animals killed fourteen days or more after the last lead treatment showed measurable amounts of lead in the blood. This fact demonstrates the mobility of lead in the bodies of these animals.

A few findings are not recorded separately. Samples of hair of Rabbits 171, 172 and 206, weighing 11 gm., 11 gm., and 15 gm. respectively, contained 0.00, 0.03 and 0.06 mg. of lead; the testicles, suprarenals, and heart of Rabbit 244, showed respectively 0.06 mg., 0.04 mg., and a trace; the uterus of Rabbit 278 showed a trace, while the suprarenals and heart showed 0.04 and 0.03 mg.; minute amounts of bile from Rabbits 249 and 278 failed to show lead.

The diminution in the actual quantities of lead found in the tissues as a result of excretory processes is best demonstrated by the amounts found in the entire carcasses of Rabbits 242, 244, 250, 255, 206, and 254 (see Table VII, showing the excretory data). It may be noted that after a period of five or six months, there is little evidence of a further drop in the total amount of lead. The explanation of this fact is plain, when reference is made to Tables II and III. An equilibrium had been established with an environment in which lead absorption was unavoidable. We shall return to this point in the data on excretion, but it must be stressed here, that the presence of such amounts of lead, months after its experimental administration, must not be interpreted as evidence of its retention by the tissues. It is the product of the two opposed processes of lead ingestion with food, and lead excretion.

Table IV presents the analytical data on two rabbits which received a suspension of lead orthophosphate intravenously, and on three rabbits similarly injected with secondary lead phosphate. The dosages indicated are approximations. The discrepancies between the recorded dosages and the

*The skin, mixed tissues, and other small tissues not enumerated have been discarded. Therefore the amounts of lead in the entire carcass of the animals are not available.

amounts of lead recovered are explainable on this ground, and for the additional reason that the lungs, skin, feet, ears, and the mixed tissues were not subjected to analysis.

The distribution of the finely divided insoluble lead salts is similar to that of the soluble salts during the first few hours, except that it shows less variation. In every case a large proportion of the lead was recovered from the liver. The amounts in the kidney were small, both in concentration and in the absolute, while the concentration in the spleen was uniformly high. The blood concentration was relatively low and did not obscure the character of

the distribution. (These animals were bled to the point of exsanguination, since none of them died in consequence of the administered lead.)

The time factor in the case of Rabbit 241, gives a special significance to the distribution of lead in its tissues. Thirty-seven days after the injection of secondary lead phosphate, over half of the lead found in the tissues was present in the liver, while less than a third of the recovered lead was found in the skeleton. The total lead recovered is equally remarkable. Little lead had been sufficiently mobile either to redistribute itself into other tissues or to be excreted. The behavior of this lead compound is therefore distinctly different from that of the soluble salts.

The results obtained after the injection of stabilized colloidal lead orthophosphate appear in Table V. Despite the higher dispersion of the particles of the lead compound, no difference in behavior was noted as compared with crystalline suspensions of lead phosphates. A more complete picture of the distribution of lead is presented in that a larger number of tissues appear in the analytical data, but the essential character of the slow migration of lead is unchanged. Again the liver is the chief depository for the injected lead, and again this organ retains a large proportion of its lead for thirty days. The bones slowly gain lead, though it is clear that at some time after the first week they begin to lose it more rapidly than they gain it. It appears that the lungs and the spleen give up all but a small amount of their initial lead, though this apparent trend may be due to the variability in the initial deposition of lead in these tissues. There is no question, however, that the liver and the spleen are more effective filters for the particulate lead than are the lungs and the kidneys.

The study of the activity of colloidal lead brings to light a series of changes in the distribution of lead which resemble those which occur when soluble salts of lead are injected intravenously. Table VI presents the facts. The initial distribution of lead is not remarkable. Rabbits 366 and 365 give a better concept of the early state of affairs than do Rabbits 369 and 368. (Rabbit 369 died from the injection with a high concentration of lead in its blood, while Rabbit 368 was found dead and could not be bled. The blood which was present in the tissues of these animals tends to obscure the picture.) Seven days after the injection, a significant loss of lead from the body had occurred, accompanied by a redistribution of lead in the tissues. Thus the kidneys show little lead, the amounts found in the liver are small in relation to the total lead content of the body, and the spleen shows only traces of lead. The bones, on the contrary, had gained more lead than they had lost. (The amounts of lead recovered from Rabbit 365, as well as the distribution of lead in the tissues, are atypical. This is not chance, but the consequence of lead present in the tissues before the experimental treatment, as shown by the fact that the recovered lead is greater than the amount injected.)

The analytical findings in Rabbit 363 give evidence of further changes in lead distribution. Rabbit 362 undoubtedly had lead in its tissues before treatment, but in addition to this factor its lead excretion was small as compared with Rabbit 363 (Table VII). The facts are evident, nevertheless, when the original amounts in the tissues are obtained by the summation of

the lead recovered from the tissues and the excreta. On this basis, Rabbit 362 had 13.7 mg. of lead in its tissues at the outset. This was redistributed in its tissues in substantially the manner shown by other animals of the series, but only 6.45 mg. were excreted. Rabbit 363 had 11.87 mg. originally but in the process of redistribution, it lost 8.88 mg. through excretion.

†Not included in total excretion.

‡Including contents of alimentary tract not shown in table.

The analytical results on the animals which were sacrificed at the end of six months are like those shown after a corresponding interval in Table I.

The analytical data obtained from the study of lead excretion following intravenous administration of lead compounds, are shown in Table VII. The excretory response of the animals treated either with lead chloride or colloidal lead was prompt and definite. The two series of results are not directly comparable, because the urine and feces were not collected separately in the case of the animals treated with lead chloride, but they are of the same general order of magnitude. (For reasons which will appear later, the results on the lead chloride animals must be regarded as merely indicative of a trend which is not necessarily accurate in its details.) In sharp contrast, the lead excretion of the animals treated with colloidal lead orthophosphate showed little or no increase. A slight elevation of the excretory rate in the feces appears to have resulted, if the findings are compared with those obtained on normal rabbits, while the urinary lead, though slightly higher than

that of the control animal studied at the same time (Rabbit 361), is little above that of normal animals observed on other occasions (e.g., Rabbits 364 and 373).*

These observed facts are in harmony with expectations based on the chemical properties of the several lead compounds, and they are in accord with the result obtained by Bischoff⁴ and his associates in their determination of the toxicity of lead orthophosphate, colloidal lead and certain soluble lead salts.

*Fecal lead output cannot be regarded as an expression of the excretory activity of the tissues because of the variability in the lead content of ingested food. Practically all food substances contain small amounts of lead, most of which is unabsorbed. Contrary to general opinion as expressed in experimental procedures, such lead occurs not in traces, but in readily measurable amounts of high variability. For this reason, we must rely mainly upon the urinary lead excretion for the interpretation of these experimental results, although we may use the alimentary lead excretion of control animals as a means of estimating the approximate magnitude of the ingested lead. The recognition of these facts has led us to separate the urinary and feces in all our recent animal experiments and to base our conclusions as to excretory processes chiefly on the urinary findings. The work on lead chloride was nearly completed before we became aware of the importance of the lead in food materials.

The findings in the tissues and in the excreta of human subjects who were treated with colloidal lead compounds are essentially like those obtained in the animal experiments. Table VIII gives the distribution of lead in the tissues of a patient treated for carcinoma of the cervix uteri by the intravenous administration of colloidal tri-lead phosphate. The last dose was administered six days before death. A comparison of the distribution of lead in the tissues of this patient with that found in a rabbit sacrificed one week after similar treatment, shows a high degree of correspondence. A large proportion of the lead was found in the liver, and relatively little in the skeleton, despite the time elapsing between the administration of the first two doses of lead and the death of the patient. Obviously the transfer of lead from

Cancer tissue	235.0	0.04	0.02-	0.12
All tissues	4904.7	21.17	0.43*	

*This figure is faulty because of the small amounts of bone and muscle subjected to analysis. Calculating the total lead in the body on the basis of estimates of the total weights of bone and muscle (approximately 8 and 20 kilograms respectively) the total lead approximates 70 mg. Pb. in a body of 50 kilograms of estimated weight. The gross concentration thus becomes approximately 0.14 mg. Pb per 100 grams. The ratio is calculated on this figure.

the liver (and the spleen) into the bones had been taking place slowly. Furthermore, little had been excreted. The calculation of the total lead in the body is somewhat inaccurate because the actual weights of bone and muscle were not available, and the bones which were analyzed (ribs and sternum) may not have been representative of the lead content of the skeleton in general. Despite these considerations there is no doubt of the essential correctness of the picture when the findings and calculations are compared with those which appear in Table IX. The latter table (IX) shows the results obtained in the analysis of the tissues of a patient whose death from carcinoma of the breast occurred seventeen days after a single intravenous injection of colloidal lead. There are certain differences in the distribution of lead in the tissues in the two cases, viz.; the patient treated with colloidal lead shows a higher concentration of lead in the kidneys, muscle, and heart muscle, a lower concentration of lead in the liver, spleen and bones, and a smaller total amount of lead in the combined tissues. Evidently lead has migrated more rapidly and more generally in the body of the patient treated with col-

*Correction of this figure must be made as in Table VIII. On the basis of total weights of fat, bone and muscle (approximately 11, 9 and 24 kilograms respectively) the total lead in the body was approximately 64 mg. In the body (approximately 70 kilograms) the calculated concentration would be 0.09 mg. Pb per 100 grams. The figures in the last column are based on this calculated concentration.

*This figure is corrected as in Tables VIII and IX in terms of total weight of bone (12 kilo.) and total weight of the body (80 kilo.). The total lead comes to approximately 135 mg., giving a concentration of 0.17 mg. per 100 gm. of the entire body. The ratios recorded in the last column are calculated on this basis.

loidal lead than in that of the patient treated with colloidal lead phosphate. It should be noted that there was no selective absorption of lead in the tissue of the tumor in either instance.

The types of distribution of lead shown in Tables VIII and IX are different from each other. Yet both are distinctly unlike that which is found when the usual type of lead absorption, over a period of time, has taken place. Undoubtedly, the character of the distribution of lead in human tissues may be found to vary greatly with a number of factors. Nevertheless when a condition of approximate equilibrium with respect to a prolonged and regular lead absorption has been brought about, the end-result is similar to that which is illustrated in Table X. The data presented in the table were obtained from the analysis of the tissues of a healthy young man who died immediately after a stab wound of the heart. His occupational history gave no evidence of recent industrial exposure to lead.

In Table XI the urinary excretion of lead following the injection of colloidal lead phosphate and colloidal lead are compared. Case A. A. showed no appreciable increase in urinary lead output following the administration of 3 doses totaling 68.4 mg. of lead as colloidal lead phosphate. This fact coincides with the data of Table VIII which show that most of the adminis-

tered lead was retained in the tissues. Case B. L. on the other hand, showed a doubtful increase in urinary lead excretion after 22.8 mg. of colloidal lead phosphate had been injected, a definite response after a total dosage of 68.4 mg. had been given, and a still further increase after the gross dosage of 163.4 mg. had been reached. Both patients who were treated with colloidal lead showed a quicker and greater elevation of urinary lead excretion than that seen in the patients who received colloidal lead phosphate. The rate of urinary excretion after the administration of colloidal lead phosphate rises slowly but steadily with each additional increment of injected lead, showing little tendency to diminish between doses. The opposite result occurs after the administration of colloidal lead. A rapid rise in the excretory rate is followed by a rapid fall in most instances. However, the rate after the initial drop is usually well above the level shown by untreated or unexposed persons. These facts are in accord with the other evidences that colloidal lead phosphate is relatively inert in the body while colloidal lead is a comparatively active compound.

DISCUSSION

The foregoing experimental observations make it apparent that the relatively insoluble tertiary and secondary phosphates of lead are chemically and physiologically inert as compared to the compounds formed in the blood when soluble salts of lead, and colloidal lead are injected intravenously. This proves that soluble lead salts are not converted quantitatively into inorganic lead phosphates when introduced into the blood stream. The conclusion that lead is carried in the blood in the form of inorganic phosphates, which was arrived at by Aub²⁰ and his associates, and by Brooks,²¹ after experimentation *in vitro*, is therefore untenable.

The results obtained on animals treated with colloidal lead show that this compound of lead is almost as reactive in the body as the water soluble salts of lead. Thus it seems probable that colloidal lead is rapidly converted into the same compounds which are formed when lead salts are injected intravenously. This conclusion is in agreement with the experimental observations of Bischoff and Blatherwick,²¹ on the toxicity of colloidal lead, and on its chemical instability under conditions similar to those which exist in the blood stream.

The usefulness of the foregoing studies to those who are employing lead compounds in the treatment of malignant tumors, will depend chiefly upon a point of view as to the mode of action of lead therapeutically. If a maintained lead stream of low concentration will combat malignant proliferation, then the use of large doses of lead orthophosphate is justified. On the other hand, if the effect of lead upon tumor tissue depends upon the maintenance of a high concentration of chemically reactive lead in the blood or in the tumor, compounds of lead which are less inert than lead phosphate should be employed. The use of such compounds will certainly give rise to danger in that general lead intoxication in the patient may occur simultaneously with the toxic effect upon the tumor cells, despite the fact that the latter may be more susceptible than the normal tissues.

The hope of obtaining selective localization of lead in tumor tissues, through use of the preparations here studied, is small. The spleen and liver, as well as the lungs, may be expected to remove the greater proportion of lead from the circulation, and the originally high concentrations of lead in these tissues will diminish rapidly (except after the use of the relatively inert lead phosphates) through the migration of the lead into the skeleton, and through excretion from the body.

Finally, it needs to be reemphasized that lead compounds are not stored in living tissues in inert form. Lead continues to be excreted from the tissues until there is a balance between that which is being excreted and that which is being absorbed as the result of unavoidable contacts with lead in food materials and elsewhere. Thus it appears that the mechanisms of lead deposition and metabolism in the tissues are not different in principle from those of the common mineral elements of the body.

LABORATORY METHODS

AN ADAPTATION OF SAND FILTRATION TO THE RAPID CLEARING OF HEAVY BACTERIAL CULTURE MEDIA

G. McF. MOOD, M.D., CHARLESTON, S. C.

THE appliance pictured and described below was perfected by the author, with the assistance of his laboratory technicians, and has been used over a period of fifteen years with considerable satisfaction.

The appliance consists of (1) a filtering unit, (2) a collecting bottle, and (3) a vacuum (pressure) pump of sufficient power to produce a negative pressure of at least twenty pounds in a collecting jar of 4,000 c.c. capacity.

The filter consists of a one-gallon glass percolator, the lower end of which is calibrated to accommodate a one-fourth inch heavy walled rubber tube, of sufficient length to reach to the collecting bottle. In the bottom of this percolator is placed a perforated porcelain disc, such as is ordinarily used in a chemical laboratory and of a size that fits snugly. Immediately over this is placed a layer of medium coarse glass wool, two inches thick, and upon this five inches of hot, wet, cleaned sand of a size which will pass a No. 60 mesh screen but be retained by a No. 80 mesh screen.

The culture medium to be cleared, such as nutrient agar-agar or gelatin, is poured, while quite hot, directly upon this layer of sand.

The collecting bottle is equipped with a tightly fitting rubber stopper, with two perforations, through each of which is placed a tightly fitting glass tube about three inches long. To one of these two tubes is connected the rubber tube attached to the percolator; to the other is attached a similar heavy walled rubber tube, the free end of which is attached to the negative pressure pump.

After the pump (which may be electric, or water or hand powered) is started and a negative pressure is produced in the collecting bottle, the culture medium is drawn through the filter and to the collecting bottle, at a rather rapid rate and sufficiently clear for all ordinary bacteriologic work. If egg white is added to the medium to be cleared, the fluid delivered is clearer; the surface of the sand filter may become clogged, however, requiring that it be broken by scraping the surface of the sand with some instrument, such as a heavy stirring rod, introduced through the layer of culture medium over the sand; with which the surface is forcibly broken. This may be repeated several times, if necessary, without interfering with the efficiency of the filter.

The filter has the advantage of filtering sufficiently clear for all ordinary bacteriologic work any of the heavy culture media, including those impaired by contact with organic filter substances, such as Huntoon's Hormone Medium. The media are cleared rapidly, with practically no loss, as the filter may be run until all of the medium is drawn through the filter layers.

The filtered culture medium is unchanged chemically, as it comes in contact with no organic substance with the exception of the rubber tube connecting the

Fig. 1

percolator with the collecting bottle. In our experience this tube has caused no change. If desired, however, this connection may be made with glass tubing.

The filter may be taken down immediately after using, while still hot. The glass wool and porcelain disc may be washed in several changes of boiling water. The sand may likewise be cleaned and used again if desired.

This is the apparatus as used by us in the Bacteriological Laboratory at the Medical College of the State of South Carolina. Its size, and the amounts and sizes of the filtering materials may be changed to suit unusual conditions.

A SIMPLE AND EFFICIENT ELECTRICAL TOOL FOR SEALING MUSEUM JARS*

CHARLES D. BROWN, ALBANY, N. Y.

THE use of an asphalt cement for sealing museum jars and cells in which pathologic specimens are mounted, while comparatively recent, has proved to be so satisfactory^{1, 2} that such a cement is rapidly supplanting those composed of other constituents, especially resins, waxes, and oxides.

Experience with several types of cement, including some of those which are applied cold, indicates that cements containing asphaltum as the principal constituent give the most favorable results and meet nearly all conditions very satisfactorily. When, however, Judah's modification of Kaiserling's solution³ is used for the final preserving medium there is a tendency for the cement to become liquefied, possibly owing to the liberation of free chloroform from the chloral hydrate which is one of the constituents of the solution. Specimens preserved in solutions without chloral hydrate and sealed with the same cement have not shown a tendency toward liquefaction.

The usefulness of a cement for specimen jars depends on its insolubility, adhesiveness, tenacity, and, in its final physical state, on its plasticity. Cements reach their permanent state by evaporation of the solvent, if used, by oxidation, by a physical change upon cooling, or by a combination of two, or of all three of these processes, depending on the constituents of the original cement. It is obvious that the more quickly the final set is reached the more adapted is the cement for wet tissue mounts.

As asphaltum meets the requirements of a suitable sealing substance, the electrical tool here illustrated and described has been designed for the rapid and efficient application of cements containing it.

The applicator is suitable for sealing practically any type of museum jar and is especially useful for applying asphalt around the cell for thin pathologic mounts as prepared by Davis.⁴

Its advantages are: that it permits quicker and neater work than the usual method, does away with the use of a sand bath for heating, and, to some extent, with disagreeable odors; it is always ready for use, and can be kept in any drawer or receptacle with other tools. Further, one or many containers can be sealed at any time without the usual preliminary preparation or manipulation of the cement. The rectangular jar is prepared in the usual manner; the surface being cleaned first with soap and water, then with absolute alcohol and benzol. It is heated with a flame until hot to the touch, the cement is applied, and the previously heated lid put on and weighted, to insure a thin joint, thus minimizing the amount of surface which can be acted upon by the preserving solution.

*From the Division of Laboratories and Research, New York State Department of Health.
Received for publication, December 8, 1932.

Manipulation of the applicator is as follows: The reservoir is filled from the stock container with liquefied cement to a level just above the sluice leading to the point; the apparatus is then tilted back far enough to prevent the cement from flowing out. The current is turned on and the cement allowed to come nearly to the boiling point. The tip of the applicator is then drawn along the top of the jar near the outer edge and the required amount of cement, which can be regulated by the speed at which the applicator is moved, is thus deposited on the surface to be sealed. An excess of cement, or applica-

FIG. 1

FIG. 2

tion too near the inner edge, may cause superfluous material to be squeezed into the jar when the lid is pressed down. A little practice is needed to gauge the speed and angle at which to operate most satisfactorily.

DESCRIPTION OF THE APPARATUS

The apparatus is 1 by 2 by 11 inches over all and weighs one pound. It is composed of a body, which contains the heating element, a tip or applying point with a sluice connecting with the reservoir for the cement, and an operating handle of wood (Fig. 1). The applicator is milled from a cored alumi-

mium casting, the dimensions of which are shown on the plan (Fig. 2). The casting was made in a commercial foundry, the shaping, finishing, and electrical work being done in the laboratory machine shop. The heat is supplied by a 150 watt cartridge heating unit placed well forward under the reservoir to insure adequate heating of the point. Such heating units operate on 110 volts, 60 cycle alternating current. As may be noted on the drawing, the applicator base, which is of brass, is removable, in order to facilitate the machine work in the heating chamber. The greatest efficiency in heating is obtained when the unit is in contact with the surrounding metal, but, owing to the difference in the expansion of the metals, a clearance of $\frac{1}{10,000}$ of an inch must be allowed when the chamber is milled. The lead should be asbestos wound and not rubber coated, as there is more heat in the chamber and handle than rubber will withstand.

A SIMPLE AUTOMATIC SHARPENER FOR MICROTOME KNIVES*

TRACY J. PUTNAM, M.D., BOSTON, MASS.

THERE can be few histologists who have not hoped to find a more efficient method of sharpening microtome knives than the usual hand honing and stropping. The need has been partially supplied by the automatic machines of Fanz,¹ but they are open to two objections. The cost of the apparatus, especially of the machine for larger knives, is prohibitive for many laboratories, and the knife blade is subjected to more wear at the edge of the disc than near the center. The device to be described can be assembled for less than thirty dollars from materials available at any large hardware store, and can easily be adapted for knives of any size.

The principle employed was suggested to me by Dr. Samuel Orton, who built a somewhat similar apparatus, and I most gratefully acknowledge my indebtedness to him. My own additions have been purely mechanical ones.

Sharpening is carried out by resting the edge of the knife against a revolving fiber cylinder (Fig. 1, A). The cylinder consists of a "Rockwood" fiber pulley, 9 inches in width and 8 inches in diameter, which has been turned down in a lathe to an absolutely true surface. These pulleys are made for 2 inch shafting, which is too large for convenient use. A $\frac{1}{2}$ inch shaft,

*From the Department of Neuropathology, Harvard Medical School.
Received for publication, December 14, 1932.

bearing two 2 inch pulleys as bushings, is inserted in the bore of the large pulley, and is quite strong enough to carry the weight involved. The shaft in turn revolves upon two bronze pillow blocks.

The cylinder is turned by a $\frac{1}{4}$ h. p. motor by means of a V belt. A motor pulley of 2 inches and a shaft pulley of 8 inches provide a suitable reduction.

If the knife is merely laid on the cylinder, it inevitably becomes grooved by irregularities of the surface. It must be given a slight lateral motion, of about an inch in each direction. This is accomplished by attaching the knife holder to a $\frac{1}{2}$ inch shaft which slides back and forth in pillar bearings, parallel to the cylinder (Fig. 1, *B*). The reciprocating motion is obtained from a crank actuated by a bevel gear lying in the plane of the base of the machine,

Fig. 1.—Knife sharpener seen from above. *A*, Polished fiber cylinder; *B*, reciprocating shaft; *C*, reciprocating mechanism made from a hand drill; *D*, knife holder; *E*, "filler" fitting inside knife holder to adapt it to knives of different sizes.

and actuated by a small belt and pulley from the cylinder shaft. A cheap hand drill furnishes bevel gears of a convenient size (Fig. 1, *C*).

The knife holder itself is the only part of the apparatus which cannot be purchased ready for use. It consists of a square rod of metal the length and thickness of the back of the largest knife to be sharpened, to which are riveted two flat pieces of spring bronze of equal length and wide enough to hold the knife firmly without striking the cylinder; that is, the edge of the holder comes within about half an inch of the edge of the blade. The bronze strips are bent toward each other so as to hold the knife firmly (Fig. 1, *D*). If smaller knives are to be sharpened also, a small metal "filler" is used, which fits inside the holder and holds the edge of the small knife at a suitable angle to the surface of the cylinder (Fig. 1, *E*). The knife holder swivels on a rod rigidly attached at right angles to the reciprocating shaft. The distance from the reciprocating shaft to the holder is adjustable so that the optimum angle

for the edge of the knife may be found by trial. A weight of about a kilogram should be placed on the rod close to the knife holder to increase the pressure of the blade against the strap (not shown in the illustration).

The only abrasive which is safe to use with this apparatus is jewelers' rouge, made into a thin suspension with castor oil. Nicks no deeper than the honed edge may be removed in ten hours' grinding or less, and no deep grooves are cut. The rouge should be employed as little as possible, however, and carefully washed off with soap and water after use, as a better polish may be obtained with no abrasive at all. A mixture of equal parts of linseed oil and turpentine with a little Japan dryer makes a good dressing and the cylinder gradually acquires an "oil polish." Great care should be taken to keep it clean. It would doubtless be easy to prepare a second cylinder to be used with emery, but this has not proved necessary so far.

Fig. 2.—Side view of machine. Parts lettered as in Fig. 1.

The angle of the knife should be so adjusted that the polished edge is about 0.5 mm. wide. If it is much wider, a trying "false edge" will form. As the edge is slightly concave, it is sharper than one of similar width produced on a flat hone. The knife should be stropped on one side until only a trifling unevenness is seen under the microscope, then an approximately equal length of time on the other. Wear on the blade is very slow and the machine may safely be left running overnight. When the edge is absolutely straight, the knife is run alternately on one side, then on the other, for a few seconds each during about a minute to remove the burr. A final polish is given by stropping for a minute to remove the burr. A final polish is given by hand on a soft strop free from dust or abrasive. The resulting edge is as perfect as can be produced.

The machine may be mounted on the wheels of a toy wagon for easy transportation.

Summary.—A simple automatic sharpener for microtome knives is described, which employs a revolving cylindrical fiber strip. The machine saves most of the labor of sharpening and produces a better edge than can be produced by hand. It is less expensive to build, more compact, less fragile and easier to use than machines now in use, and can be adapted to the largest knives.

MORPHINE PENTOBARBITAL ANESTHESIA FOR DOG SURGERY*

M. H. SEEVERS, M.D., MADISON, WIS.

A NONVOLATILE anesthetic combination for dogs, which produces good surgical anesthesia and relaxation for a period of from one to two hours and assures postoperative recovery, is a distinct asset to the individual experimenter.

The short-acting barbiturates, pentobarbital and amytal, if used alone, give good anesthesia but recovery cannot be expected for from three to six hours. In addition, since these drugs are not analgesic, undesired restlessness and purposeless movement often characterize the recovery period.

We have been using in this laboratory a combination of morphine and pentobarbital sodium with gratifying results. The anesthetic dosage of pentobarbital sodium for the dog is from 0.025 to 0.035 gm. per kilogram intravenously. If morphine sulphate 0.01 gm. per kilogram and atropine sulphate 0.001 gm. per animal be given subcutaneously one and one-half hours prior to operation, the amount of pentobarbital sodium required is reduced to 0.005 to 0.015 mg. per kilogram, depending on the length of anesthesia required. Obviously, no fixed dosage can be predetermined for any given animal because of individual variability in reaction to the drugs.

When ready for operation, we inject intravenously a 1 per cent solution of sodium pentobarbital slowly, carefully observing respiration and other criteria of anesthesia, particularly the lid reflex. Slow injection (five minutes) permits of maximal control of depth of anesthesia with minimal dosage. The minimal amount of the drug required to produce anesthesia, if given in this manner, will usually last about one to one and one-half hours. Subsequent additions of this barbiturate by the same method of slow injection will extend the period of anesthesia if desired. Precaution against respiratory arrest must be taken by using slow intravenous injection of the drug on a symptomatic basis rather than by rapid administration of a fixed dose.

Recovery is gradual (one to two hours) and is free from excitement. Pharyngeal and laryngeal reflexes return early leaving no concern as to care or ultimate result from anesthetic procedure. We have found this combination highly satisfactory for any physiologic experiment in which the presence of morphine or a barbiturate is not specifically contraindicated.

AN IMPROVED METHOD OF BLOOD CULTURE*

LEONARD S. MANLY, AND CLARENCE C. SÆLHOF, M.D., CHICAGO, ILL.

THE following method of making blood cultures has given satisfactory results: A bottle, approximately 250 c.c. in size and containing 30 c.c. of dextrose phosphate broth, is fitted loosely with a two-hole rubber stopper bleeding attachment, the inlet tube of which should extend for about 6 cm. into the bottle, and which should have attached a No. 13 gauge needle, and

FIG. 1

is sterilized at a pressure of fifteen pounds for thirty minutes. Just before use, as recommended by Hadjopoulos and Burbank,¹ 10 c.c. sterile peptone solution, containing 2 drops of 5 per cent sterile sodium carbonate solution, are added. The rubber stopper is then fitted tightly and tied into position. The apparatus is now ready for use (Fig. 1). Into this bottle approximately 130 c.c. of blood is drawn from a suitable vein. The bottle is left to stand at room temperature for three hours in order to secure a firm adherent clot; it

*From the John McCormick Institute for Infectious Diseases.
Received for publication, February 2, 1923.

is now incubated at 37° C. and examined carefully each day for the growth of small pinpoint colonies on the edge of the clot or in the surrounding fluid. For identification of eventual growths, streaks on suitable mediums can be made. Using this method positive cultures were obtained in 43 of 67 cases (64 per cent), while the usual routine method yielded positive blood cultures only in 14 cases (21 per cent).

The advantages of the new method are (1) neutralization of natural complement or alexin of blood directly upon withdrawal by the peptone sodium carbonate solution¹; (2) direct transfer of blood to cultural medium with minimum handling and consequent lessened possibilities of contamination; (3) all gradients of oxygen tension necessary for the growth of different types of bacteria are provided; and (4) the ease of observance of growth.

THE PREPARATION AND STAINING OF FROZEN SECTIONS*

A. A. THIBAudeau, M.B., BUFFALO, N. Y.

FOR some considerable time there has been much discussion as to the relative value of the various methods used in the preparation of tissues for section and in the methods of sectioning the same. The Pathological Laboratory of the State Institute for the Study of Malignant Disease has for many years been one of the foremost champions of the frozen section method, and as we have many enquiries on this topic, it has seemed desirable to describe in some detail the actual technic in use in our laboratory with some discussion of results obtained and our reasons for the preference of this method.

During the past twenty years tissues from more than 125,000 surgical cases and from almost 1,000 autopsies have been sectioned by the frozen technic in the pathological laboratory of the Institute. Modifications in both the methods of cutting the section and in the technic of staining have been made from time to time, but our efforts have been primarily directed to the preparation of better sections rather than to the reduction of the time necessary to secure the same.

The frozen section method was at first advocated for its rapidity of execution. It was the only method practical for immediate diagnosis of suspicious tissue while a patient was held under anesthetic on the operating table, pending the report of the pathologist. Small portable microtomes were devised and these were especially designed for use in constricted quarters. With such equipment it was obviously difficult to obtain satisfactory or uniform sections. Where speed was the only objective, the quality of the sec-

Received for publication, January 26, 1933.

tion produced suffered; and this very fact caused many of the older and more experienced pathologists to condemn the method in its entirety.

While these objections were early realized in our laboratory, the desirability to the attending surgeon of prompt reports on biopsy material was also appreciated. Serious attempts were made to so modify and use the frozen section method that examinations could be promptly made without, in any way, sacrificing the quality of the section. At the present time we feel that our routine frozen sections are equal if not superior to sections produced by any other technic.

A prime necessity in the production of good sections is a suitable microtome. We have long since discarded the light, flimsy, portable type of microtome for a more solid instrument. At present we use a large sledge microtome, Spencer No. 860, which we have had modified so that we may use a freezing chamber. Sections produced on this rigid instrument are uniform in thickness

Fig. 1.—Photomicrograph made from a frozen section of a myxochondro-epithelioma. Stained with hematoxylin and eosin.

and can be consistently cut on properly fixed material at from $5\ \mu$ to $10\ \mu$. A sharp knife is, of course, essential. We employ 18 cm. and 25 cm. knives which are systematically examined and stropped each day before use. If any serious defect in the cutting edge is noted, the knife is laid aside for thorough sharpening.

FIXATION OF TISSUES

To secure good sections the tissue to be examined must be properly fixed. For the frozen technic, this is best accomplished by the use of 10 per cent formalin on thin slices of tissue. Where used, alcohol or other chemical fixative must be thoroughly removed by washing in water or other suitable solution. In the preparation of material for section the following steps are indicated:

1. Thorough fixation of the gross material preferably in 10 per cent formalin solution.

2. Careful inspection by the pathologist of such material with a view to the selection of suitable blocks for section.

3. Removal of blocks of tissue 1 cm. to 2 cm. square by 2 mm. to 3 mm. thick, and including if possible normal as well as pathologic portions of the tissue.

4. These blocks should be held in 10 per cent formalin until sectioned.

FREEZING OF TISSUES

For the freezing of the tissues carbonic oxide is used exclusively in our laboratory. We have found that tissues must be frozen to just the right consistency. If they are frozen too hard, the sections are apt to be brittle and to break up readily; if too soft the knife scrapes, rather than cuts the tissues and sections are not satisfactory. Various solutions of glucose, dextrin, gelatin, etc., have been used as embedding materials on the freezing stage, but we have

Fig. 2.—Adenoma of thyroid. Photomicrograph made from frozen section. Hematoxylin and eosin stain.

not found any of these to be of great practical value. Water in just sufficient quantity to fix the tissue firmly to the freezing stage has proved most satisfactory and any tissue too friable to give satisfactory sections in this medium alone should be immediately started through the paraffin or celloidin embedding process.

CUTTING OF THE SECTIONS

1. Insert a freshly stropped knife in the holder and systematically tighten all screws holding the knife and the freezing stage of the microtome. We have found that the best sections are secured when the knife is inclined at about 25° to the horizontal and when it sweeps over the block of tissue at an angle of approximately 30°

2. Set the microtome indicator at the proper point, 5 μ , 8 μ , 10 μ .

3. Rinse the block of tissue in distilled water and place in a small drop of water in proper position on the freezing stage.

4. Admit CO_2 to the freezing chamber in short blasts until the water and tissue *start* to freeze. Before the tissue is completely frozen the block is trimmed by bringing the knife over its surface, cutting away excess elevations and leveling the block.

5. When the tissue is well frozen, sections are secured in the usual manner by successive strokes of the knife.

6. Remove sections from the knife with the finger tip or with a wet camel's hair brush to a 10 per cent alcohol solution in a small Petri dish.

STAINING

Sections prepared as above are stained as follows:

1. Deliver sections into a flat Petri dish in the 10 per cent alcohol solution.

2. Transfer whole untorn sections into a shallow staining dish containing a solution of Harris hematoxylin, for from five to fifteen seconds.^{a, b}

a. Harris hematoxylin which we have found most satisfactory for routine staining is made up as follows:

Hematoxylin	5 grams.
Alcohol 95%	50 c.c.
Dissolve	
Ammonium Alum	100 grams.
Distilled Water	1,000 c.c.

Boil alum until dissolved: add hematoxylin. Bring whole to a boil. Then add 3 grams mercuric oxide (HgO) and cool *quickly*. The above is stock solution. For routine staining it should be further diluted as follows:

Hematoxylin (Stock)	300 c.c.
Glycerin	50 c.c.
Glacial acetic acid	12 c.c.

This stain darkens with age and is usually better a few days after preparation. When it becomes too dark, it is discarded and a fresh solution prepared from stock.

b. The placing of the staining dish over a window of the same diameter in the laboratory table and below which a 50 watt electric lamp is placed, gives a satisfactory illumination of the staining dish and allows sections to be handled more easily and more expeditiously.

3. Remove sections with straight section needle to large Petri dish containing fresh distilled water. Leave until all excess stain is washed out. Gentle agitation facilitates this process.

4. Transfer to a second Petri dish containing distilled water to which a few drops of NH_4OH have been added. In this solution the sections at once change from a purple to a blue color.

5. Sections are lifted, in rotation, into dishes containing 70 per cent, 85 per cent, and 95 per cent alcohols respectively, being left a few seconds in each.

6. Counterstain in third saturated solution of eosin in absolute alcohol for five seconds.

7. From the counterstain, sections are transferred for clearing to carbol xylol contained in a fairly large deep staining dish. From this solution they are mounted directly on the slide without the use of a section lifter.

8. Blot sections with filter paper and mount in balsam. This whole process of sectioning, staining and mounting can be carried out in less than five

Fig. 3.—Giant cell tumor, epulis. Frozen section. Hematoxylin and eosin stain.

Fig. 4.—Squamous-cell carcinoma of skin. Photomicrograph made this year from frozen section made, stained and mounted in 1913, and in our files since that time. Staining by hematoxylin and eosin.

minutes. We have in some profusion tried out the various rapid methods using fresh unfixed tissues, polychrome stains, special embedding media, etc., but have not found any of them to give the same satisfaction as do fixed tissue sections stained with hematoxylin and eosin. The latter, moreover, give us permanent sections which retain their stain satisfactorily over long periods of time and which are of value in the permanent record of the case.

TABLE DIAGNOSIS

While in our laboratory we are of the opinion that the so-called "Table diagnosis" performed during operation is undoubtedly in many cases of great value to the surgeon, we feel that if this procedure is to be used, accuracy should be the primary consideration. Sufficient time should be allowed the pathologist to thoroughly examine the tissue in the gross and to select and properly fix the pieces of tissue for section. Our method in these cases is to fix small blocks, not more than 2 mm. thick or 1 cm. square, of selected tissue in strong formaldehyde solution which is kept at the boiling point. Fixation is usually satisfactorily accomplished in about fifteen seconds. We then proceed with the regular freezing and staining technic. Reports can usually be made on such tissues in four or five minutes from the time the tissue is handed to the pathologist. We feel strongly that the few additional moments necessary to allow the pathologist to make a careful survey of the tissue presented to him and to prepare and stain a section satisfactory for microscopic examination is, indeed, time well spent. If, on the other hand, the surgeon is unwilling to allow sufficient time for this type of examination, we are of the opinion that the whole procedure might better be abandoned.

Frozen sections when properly made and stained show on examination a brilliancy of staining which is attained by no other method of preparation. Due to a minimum subjection to chemicals, heat, etc., the cells retain their original size and shape to a much greater extent than is the case in paraffin or celloidin embedding. For the same reason also, sections prepared by the frozen technic are much more permanent than those prepared by any other method. Sections in our files for more than twenty years are today as well stained and as satisfactory for diagnosis as when first prepared. In fact, to some extent aging seems to improve these sections. During the past few years many photomicrographs have been made for the illustration of scientific articles from sections made routinely in the laboratory by frozen section technic. That this method is as satisfactory as any other for the purpose of photomicrography is demonstrated by several photomicrographs recently made from sections made during the usual laboratory routine. We also submit a photomicrograph of a section of a pearl forming squamous cell carcinoma which has been in our files for more than twenty years.

A SIMPLE AUTOPSY STAND FOR MICE*

(MISS) J. M. HUTCHESON, TORONTO, CANADA

UNDER the heading "Laboratory Aids" Dr. Raymond H. Goodale described in this JOURNAL (18: 422, 1933) a mouse holder made by nailing four spring-type clothespins to a piece of board. We find that such a holder is admirably suited for guinea pigs but for mice prefer one which is made from the cover of a Petri dish and four "Regal" paper clips. Two of these clips are

Fig. 1

slipped onto the rim on opposite sides of the dish, and the mouse's legs are drawn through the central slits of the clips. Fig. 1 shows the mouse in position and the type of paper clip which is used.

The advantages of this method are that the holder can be set up and disassembled in a moment; that infective material, such as washings from the peritoneal cavity, collect in the dish; and that after use the holder and mouse can be dropped into the ordinary basin of disinfecting fluid.

DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

PNEUMOCOCCUS, Specific Precipitation Test for Standardization of Type I Antipneumococcus Serum, Brown, R. J. Immunol. 25: 149, 1933.

Forty-six Type I antipneumococcus sera were tested for precipitative activity with a solution of the Type I cellular carbohydrate. The results obtained agreed in 91.3 per cent of the cases with the results obtained by mouse protection tests. Eight concentrated antipneumococcus sera were similarly tested and found to agree in seven instances. The results indicate that the precipitation test described provides a titration which appears to be a reliable index of the development of the protective activity in the course of immunization; in the preliminary evaluation of the serum it can thus replace the more complicated protection test which, at present, however, should still be used in the final standardization.

SALMONELLA SUIPESTIFER, Infections in Man. Kuttner, A. G., and Zepp, H. D. J. A. M. A. 101: 269, 1933.

Four more cases of *Salmonella suipestifer* infection in man are reported: One in an adult and three in children. The adult developed a suipestifer septicemia and cystitis, following a radical antrum operation. Two of the children had arthritis and one of them showed osteomyelitis. The other child developed a suipestifer septicemia accompanied by severe purpura, during the course of bronchopneumonia. No complications such as arthritis, osteomyelitis, cystitis and purpura were observed in the group of cases reported by the authors in 1932. It is of interest that this organism, *Salmonella suipestifer*, Group II, can produce arthritis and osteomyelitis unaccompanied by fever.

Purpura has been observed as a rare complication in paratyphoid B fever. In none of the cases of suipestifer infection in man described in the literature has severe purpura with complete disappearance of platelets been described such as occurred in Case 2. Since purpura is a common symptom of pigs infected with the hog cholera virus, it was thought possible, in view of the interstitial bronchopneumonia found at autopsy, that in this patient *Salmonella suipestifer* might have been associated with the virus of hog cholera. Unfortunately, no experiments to determine the presence of the virus were undertaken. On the other hand, it is entirely possible that the purpuric manifestations were merely the result of a severe infection in a debilitated child and that some virus other than that of hog cholera was responsible for the pathologic picture in the lung. None of the other cases showed any evidence of purpura, and their platelet counts were entirely normal.

Three of the patients live in Baltimore; one lives in the country. In no instance was any association with infected pigs established, and none of the cases had any contact with each other. There was no history of a similar illness in any other member of the family, although the mother of one of the patients agglutinated the organism isolated from her daughter.

The organisms isolated from these four cases all belong to Group II, *Salmonella suipestifer*, although Group I is generally considered the American type, most commonly associated with hog cholera in this country. In recent years, however, Group II has been associated with increasing frequency from infected pigs in the United States.

URINE: Practical Method for Simultaneous Demonstration of Lactose and Glucose in, Kleiner, I. S., and Tauber, H. J. Biol. Chem. 100: 749, 1933.

To 1 c.c. of urine in a graduated 20 c.c. cylinder, 1 c.c. of a 4 per cent solution of copper sulphate is added, and then enough barium hydroxide solution to make the fluid faintly alkaline to litmus (approximately P_H 7.5 to 8); 5 c.c. is usually sufficient. Enough

water is added to make a total volume of 20 c.c. and the solution is mixed and filtered. If a faint opalescence persists, the results will not be affected and the trace of barium present need not be removed for either of the two determinations to follow. Two cubic centimeters of this filtrate is pipetted into a Folin-Wu sugar tube. Two similar tubes are prepared for standards, one of which contains 0.2 mg. of dextrose in 2 c.c. and the other 0.4 mg. of dextrose in 2 c.c. To each of the three tubes 2 c.c. of monose reagent is added and the tubes are heated in boiling water for eight minutes and cooled for two minutes. This reagent consists of a 1 per cent solution of barium hydroxide, to which is added 5 drops of a 1 per cent solution of sodium bisulphite for each 25 c.c. of reagent just before it is used. Another set is run with the Benedict alkaline copper reagent simultaneously, with the same amounts of filtrate, standards and reagent, boiling for six minutes and cooling for two minutes. To each of the tubes in both sets 2 c.c. of Benedict's color reagent is added and mixed with the contents. The tubes are allowed to stand for two minutes, water is added to the 25 c.c. mark, the contents are mixed thoroughly and colorimetric comparisons are made. If the color is too dark, the determination must be repeated with diluted urine for the copper-barium precipitation. With this procedure the monose method yields dextrose values that correspond closely with values obtained by the Benedict method.

BLOOD, Iron in Human. Sachs, A., Levine, V. E., and Apelsis, A. *Arch. Int. Med.* 52: 366, 1933.

The average iron content of whole blood, based on analyses of samples from 100 normal men, is 50.01 ± 2.56 mg. per hundred cubic centimeters. The average for 50 normal women is 42.67 ± 2.13 mg. per hundred cubic centimeters. The blood of women has a definitely lower iron content than that of men.

Iron in whole blood is almost entirely linked with the hemoglobin molecule. Since the quantity of nonhemoglobinous iron present in the serum and the cellular elements is very small, the error in calculating hemoglobin from whole blood iron is negligible.

On the basis that hemoglobin contains 0.335 per cent of iron we conclude that the average normal blood of men contains 14.93 ± 0.76 gm. of hemoglobin per hundred cubic centimeters, while the average normal blood of women contains 12.74 ± 0.66 gm. per hundred cubic centimeters.

By dividing the number of milligrams of iron per hundred cubic centimeters of blood by the first three figures of the red blood cell count, a quotient, which Murphy, Lynch and Howard designated as the iron index, is obtained. We have found the iron index for normal men to be 10.01 ± 0.65 gm., and for normal women, 9.6 ± 0.56 gm. of hemoglobin per hundred cubic centimeters.

The iron index is preferable to the color index because of the greater accuracy with which the former may be determined.

The iron color index, based on the ratio of the percentage of iron to the percentage of red blood cells, is also preferable to the older hemoglobin color index. The advantages to be derived from the clinical use of this index lie in its accuracy and in the retention of the convenient +1 or -1 designation of the older hemoglobin color index.

The red and white cell counts, iron, hemoglobin, iron index and iron color index in 63 clinical cases are also included in this report.

TUBERCULOSIS, Comparison of Blood Sedimentation Rate and Vernes Flocculation Test in Pulmonary, James, H. M. *Med. J. Australia* 11: 265, 1933.

The work of previous writers was confirmed in that both the blood sedimentation rate determination and the Vernes flocculation test are of considerable value in the control of treatment and prognosis in cases of pulmonary tuberculosis.

Providing all precautions are taken, and with certain recognized exceptions, the figures for both tests were comparable, particularly in those infections which were comparatively early or moderately advanced only. In the very advanced cases it was felt that the Vernes test represented the clinical condition less accurately than the blood sedimentation rate.

Of the two methods of investigation, it must be considered that the blood sedimentation rate estimation is more applicable to everyday clinical work and that there is no information given by the Vernes test which cannot equally be supplied by the blood sedimentation rate.

The advantages of the blood sedimentation rate method may be summarized as follows:

1. Expense: The Vernes test, because of elaborate laboratory methods and material, is a much more expensive test than the sedimentation test.

2. Simplicity: Any medical practitioner can do a blood sedimentation test at the bedside if necessary. Results are immediate and no calculations are necessary. With the Vernes test a certain amount of calculation is necessary, the human element becoming a factor to be considered.

3. Information: The blood sedimentation rate actually gives considerably more information than the Vernes test. In the Vernes test we have an end figure only. With blood sedimentation the rate of fall of the erythrocytes is plotted every five minutes and there is nothing in the Vernes test to correspond to the information received from a study of the curve. The difference between a diagonal and a vertical curve in the sedimentation test is often of paramount importance.

4. Comfort: The one cubic centimeter technic for the blood sedimentation is a very simple matter for the patient and occasions practically no discomfort. For the Vernes test it is necessary to withdraw at least ten cubic centimeters of blood. For the Vernes test also a fast of about fifteen hours is necessary before the test is made.

5. Transport: Blood for the Vernes test must be sent to a center where there are the requisite facilities. The blood sedimentation test may be performed anywhere.

In all the author feels that the blood sedimentation test is of equal value to the Vernes test and is not subject to the same number of fallacies.

Because of its ease of application and greater information supplied, it must be preferred to the more complicated Vernes test.

AGRANULOCYTOSIS, In Childhood, Givan, T. B., and Shapiro, B. Am. J. Dis. Child. 46: 550, 1933.

Twenty-nine cases of agranulocytosis in childhood are reviewed, and an additional case is added.

The instances of agranulocytosis in children with severe antecedent infection must be regarded as a unit.

Finally, a case is presented in detail in which antecedent infection was marked and agranulocytosis was superimposed. Adenine sulphate was used to stimulate the marrow centers, with good results, for with the reappearance of the granular elements, the peripheral blood stream, from which *Staphylococcus aureus hemolyticus* had previously been recovered, became sterile. Of note is the fact that when transfusions were started there was a coincident drop in the total number of white cells and in the percentage of granular cells. One injection of adenine sulphate, however, was sufficient to cause a return of the cellular elements to their previously attained level. The patient was then able to withstand two radical operations on the jaw, and recovery was uneventful.

TRICHOPHYTIN TEST, Report of 350 Cases, Muskatblit, E., and Director, W. Arch. Dermat. & Syph. 27: 739, 1933.

Three hundred and fifty patients were tested intradermally, of whom 300 were clinically mycotic and 50 were not mycotic.

Nonspecific reactions were observed in 4 per cent of nonmycotic cases.

The trichophytin test gave a positive reaction in 72.3 per cent of cases proved mycotic by the laboratory.

Clinical diagnosis was more frequently corroborated by the test than by the laboratory examination; for example, in clinically mycotic cases the test was positive in 60.3 per cent, while laboratory examination was positive in only 39.7 per cent.

Patients with highly inflammatory lesions gave a higher percentage of positive tests; however a positive reaction was found in many cases with limited and slightly inflammatory lesions.

The test was positive in cases in which the infection was due to various fungi of human and animal types, particularly in those caused by *Epidermophyton interdigitale*.

Monilia infections of the skin also gave a positive reaction but less frequently than cases due to filamentous fungi (*Trichophyton*, *Epidermophyton*, and *Microsporon*).

The intradermal test with fungous extracts, while not absolutely specific, is of considerable value in the diagnosis of fungous infections of the skin due to filamentous as well as to yeastlike fungi.

Common fungi such as *Trichophyton violaceum*, *Microsporon audouini* and *Epidermophyton interdigitale* yield an efficacious preparation when a mixed polyvalent extract is made of freshly isolated strains.

General allergic hypersensitiveness of the skin develops not only in deep inflammatory mycoses but also in many cases of superficial type.

Epidermophyton interdigitale, the most common causative agent of dermatophytosis in the country, is apt to cause a considerable degree of cutaneous allergy.

TULAREMIA: Culture Medium for Rapid Growth of *P. Tularensis*, Foshay, L. Am. J. Clin. Path. 3: 379, 1933.

Twenty-four grams of "Difco" dehydrated brain-veal agar and 2 gm. of nutrose are dissolved with gentle heat in one liter of distilled water containing 5 gm. NaCl, 0.3 gm. Na_2HPO_4 , 0.2 gm. KCl and 0.1 gm. CaCl_2 . The mixture is divided equally among four 500 c.c. flasks and set in the refrigerator to solidify. After solidification 0.1 gm. of cystine is placed in a small pile on the center of each surface. If care is taken not to stir the cystine around, the medium may be autoclaved safely at fifteen pounds for fifteen minutes without impairing the growth-promoting property of the cystine. Upon removal from the autoclave the flasks are set in a row and each is rotated vigorously in turn until the sedimented cystine is dissolved. This usually requires about ten minutes.

If only 250 c.c. of enriched medium is desired, three flasks are capped and put in cold storage and one is cooled to about 50° C. To this flask is added 10 c.c. of 25 per cent dextrose and 30 c.c. of either ascitic fluid or any sterile serum diluted 1:5. Other flasks are melted and enriched similarly as needed. Slanted tubes are capped as soon as set to prevent water loss. If a liter of finished medium is wanted the base medium may be solidified in one large flask, 0.35 gm. of cystine added, autoclaved, cooled and enriched with 40 c.c. of 25 per cent dextrose and 120 c.c. of ascitic fluid or diluted serum.

P. tularensis will grow rapidly and luxuriantly on the surface but not in the water of syneresis. Growth on slants is best at partial oxygen tension and, because of the tendency of the slants to slump when warmed, they are incubated in a slanting position. Partial oxygen tension is obtained by the tandem arrangement devised by Wherry and Oliver.

The medium is not good for preservation. Cultures will usually not remain viable, as judged by subculturing, for more than eight days. Strains that are being carried along on it are best transferred twice a week. For isolation of *P. tularensis* from infected rodent tissues it is only fairly good, inferior to blood-cystine-dextrose agar and to coagulated egg yolk. Its chief virtues are its capacity to promote rapid and abundant growth, and the short time and ease of making. The base medium can be stored indefinitely at low temperature, and tubes of the enriched medium are good for at least three months if water loss is prevented.

PENTOSURIA, Studies In, Enklewitz, M., and Lasker, M. Am. J. M. Sc. 186: 539, 1933.

Twelve cases of pentosuria are described, the sugar in all cases being 1-xyloketose.

All cases of "glycosuria" in which the concentration of reducing bodies in the urine remains unalterably below 1 per cent should be regarded as possible pentosurias and should be further investigated.

By examining urinary specimens voided before and after the ingestion of a liberal carbohydrate meal, it is often possible to differentiate cases of mild diabetes mellitus, renal diabetes and pentosuria. Fermentation tests, and testing with Bial's reagent will give additional valuable information as to the nature of the urinary sugar.

Xyloketose reduces alkaline copper solution in the cold.

The crystalline structure of racemic xylosazone is described.

The ingestion of amidopyrin markedly increases the output of urinary pentose.

Pentose excretion is uninfluenced by modification of the carbohydrate or protein content of the diet. It is also unchanged by rest, exercise or thyroid extract administered by mouth.

When fed 5 gm. of xyloketose a pentosuric excreted but 0.5 gm. more than usual. The urine of a control taking a similar amount of xyloketose showed no reducing substance. It appears that both pentosurics and normals can utilize or destroy xyloketose when it is administered by mouth.

SEDIMENTATION TEST, In Dermatology, Tulipan, L., and Director, W. Arch. Dermat. & Syph. 27: 759, 1933.

The red cell sedimentation test was performed in one hundred and fifteen patients with conditions representing thirty-five diseases of the skin. The method of Westergren was employed.

The sedimentation rate was usually normal in lupus erythematosus and in erythema multiforme, including the bullous variety.

It was usually increased in tuberculosis of the skin.

It was invariably increased in erythema nodosum and markedly so in the eruption due to phenolphthalein.

It was increased in dermatitis herpetiformis, whereas in other generalized grouped vesicular dermatoses, including dermatophytids, it was normal.

The sedimentation rate in epithelioma varied from normal to a pathologic increase, depending on the extent of the lesion.

It was high in a case of Hodgkin's disease in which there were cutaneous lesions.

It gave borderline readings in mycosis fungoides and erythroderma.

Normal readings were obtained in some of the more common dermatoses.

On account of the increased rate in six cases of pemphigus reported by Pessoa and Ribeira and in two cases reported here the sedimentation test is suggested as a possible aid in differentiating pemphigus from erythema multiforme bullosum.

BILIARY TRACT: Diagnostic Methods and Metabolic Studies in Disease of, Twiss, J. R., and Killian, J. A. Am. J. M. Sc. 186: 418, 1932.

A routine of study for diseases of the biliary tract is presented with findings in 10 control individuals and 30 patients in whom a complete investigation showed no evidence of biliary tract disease.

This investigation has included: History, physical examination, cholecystogram, duodenal drainage, inspection of bile specimens, microscopic examination of biliary sediments, chemical analyses of blood and bile, icterus index determination, van den Bergh reactions and the bacteriologic study of bile.

The findings in both series of patients are presented as standards for comparison with findings in cases of suspected gallbladder or liver disease.

Results indicate that with a normally functioning biliary tract these tests should show:

- a. A satisfactory "visualization" of the gallbladder on roentgenographic study.
- b. The presence of 30 to 60 ml. of concentrated bile during nonsurgical biliary tract drainage.
- c. The absence of pathologic elements on microscopic examination of the biliary sediment in all specimens.
- d. Little or no cholesterol in the D₁ and D₂ bile.
- e. Bile acids of the concentrated bile fraction 4 to 7 times greater than that of the duodenal bile.

f. The absence of pathogenic organisms which occur repeatedly in bile obtained by sterile duodenal drainages.

g. A blood serum icterus index reading of 4 to 8, a negative direct van den Bergh reaction.

SCARLET FEVER, Heterologous, Trask, J. D., and Blake, F. G. J. A. M. A. 101: 753, 1933.

The authors have demonstrated, as others before them have done or suggested, that heterogeneity exists among the toxins derived from scarlatinal streptococci. However, the chief interest of this communication lies in the demonstration and study of a new scarlatinal toxin from the blood and pleural exudate of cases of scarlet fever which failed to give a therapeutic response to potent scarlatinal antitoxin.

They do not wish to imply that this is the usual cause of failure in the antitoxin treatment of the disease because they have insufficient data on the incidence of this variety of scarlet fever. However, it is significant that Dr. Wadsworth has already prepared a polyvalent antitoxin which does neutralize the new toxin and the standard Dick toxin.

As regards the clinical features of the disease in three cases, it should be noted that pneumonia developed within the first few days in each case. It is of special interest and, perhaps, not without therapeutic significance, that a large amount of toxin was found in the pleural exudate in one case. The authors believe this to be the first demonstration of scarlatinal toxin in such material. They conclude that:

1. Heterogeneity exists among the toxins found in the blood in scarlet fever.
2. Heterogeneity exists among the scarlatinal antitoxins naturally found in man.
3. Polyvalency is desirable in therapeutic scarlatinal antitoxin.

SCARLET FEVER, Effect of Tonsillectomy on the Development of Immunity to, as Shown by the Dick Test, Kereszturi, C., and Park, W. H. J. A. M. A. 101: 764, 1933.

From a study of 34 tonsillectomized children as compared to 31 controls it is concluded that from this limited number of cases, it might be said that tonsillectomy has certainly no marked effect on the susceptibility to scarlet fever within six months after it is done, as demonstrated by the changing of a positive Dick test into a negative one.

HYDATIDIFORM MOLE, Differentiation of Pregnancy and, Dabney, M. Y., Flinn, G. G., and Dabney, E. G. J. A. M. A. 101: 771, 1933.

In view of the emphasis recently laid upon the greatly increased concentration of anterior pituitary sex hormone in the urine in hydatidiform mole and chorionepithelioma, the utilization of this fact as a means of differential diagnosis in the present case report is of definite interest.

In a patient with clinical symptoms suggesting hydatidiform mole, together with a strongly positive Friedman test after the injection of as little as 0.4 c.c. of urine, a dead five and one-half months' fetus was finally expelled.

The case is of further interest from a physiologic standpoint because of the unusually large quantity of anterior pituitary sex hormone demonstrated in the urine shortly before abortion of a nonviable fetus. It is possible that abnormal excretion of this hormone regularly accompanies fetal death without complete detachment of the placenta or that the increased quantity of hormone itself brings about defective fetal development and miscarriage and should be an indication for emptying the uterus in pregnancy, when it is not a sign of hydatidiform mole or chorionepithelioma. If this laboratory finding had been taken as an indication for therapeutic abortion, the present patient, a very anemic woman, would have been spared over a week of bleeding.

Further quantitative hormone studies in cases of threatened abortion and dead fetus are desirable, and the authors suggest revision of existing laboratory criteria for the diagnosis of hydatidiform mole and chorionepithelioma.

LIVER FUNCTION: Galactose Tolerance as a Measure of, Roe, J. H., and Schwartzman, A. S. *Am. J. M. Sc.* 186: 425, 1933.

A study of the galactose tolerance of normal subjects and patients with representative types of liver disease has been made by determining the blood and urinary galactose concentration following the ingestion of galactose by mouth. Data are presented showing that following galactose ingestion, the blood galactose concentration is a better indication of liver function than the urinary galactose excretion since it is not influenced to the same extent by a variable renal threshold.

Blood galactose concentrations similar to those of normal subjects were obtained in cases of cirrhosis, metastatic carcinoma, congestive heart failure, toxic and chronic degenerative hepatitis. The urinary galactose excretion in these cases was essentially the same as observed in normal subjects. These studies indicate that the galactose tolerance liver function test may not be expected to give evidence of diagnostic value in chronic liver disease.

Blood galactose values higher than normal were observed in cases of acute catarrhal jaundice. A normal response was obtained in a case of cholelithiasis with marked jaundice. These findings indicate that the galactose tolerance liver function test may be of value in the differential diagnosis of jaundices of infectious and noninfectious origins.

Based upon these studies a new technic for the galactose tolerance liver-function test is proposed. In this test 1 gm. of galactose per kilo of body weight is given by mouth under fasting conditions and the galactose content of samples of blood collected at hourly intervals for three hours following ingestion is determined. Data are presented for the interpretation of findings obtained by this technic.

MONONUCLEOSIS, Infectious: A Diagnostic Test for, Bunnell, W. W. *Am. J. M. Sc.* 186: 346, 1933.

The presence of a rather high concentration of heterophil antibodies, demonstrable in the form of sheep cell agglutinins, has been described in the active stages of 4 cases of infectious mononucleosis. Since then tests for heterophil antibodies have been made in over 2,000 cases representing various clinical entities, including additional cases of infectious mononucleosis. The diagnostic value of the test has become increasingly evident.

The serum, from 5 to 8 c.c. of human blood obtained as for a Wassermann test, is utilized for the procedure. For sake of conformity in results it is important to use a standard type of agglutination tube. The author has found a tube 100 mm. in length and 10 mm. in diameter most satisfactory and has used it in all tests, as a slight effect upon the readings is noticed with varying sized tubes. The use of a 2 per cent suspension of sheep cells is likewise desirable, as a heavier suspension interferes with the agglutination phenomenon.

If the serum is inactivated properly and the procedure carried out as described, there should be no hemolysis in the tubes to confuse the readings. (In serum which contains bile the sheep cells are usually hemolyzed and the tests unsatisfactory.)

The author has employed the sheep cell agglutinin test in over 2,000 cases representing 76 clinical conditions. With the exception previously noted, namely, serum disease, he has been unable to demonstrate an appreciable increase of heterophil agglutinins for sheep cells in the sera above the normal dilution of 1 to 8. In 15 cases of infectious mononucleosis he has found a consistent increase in all cases. The titers, ranging from 1 to 64 to 1 to 4,096, apparently depended to a considerable extent upon the stage of the disease at which the serum was obtained and upon the severity of the illness. None of the common conditions manifesting a similar clinical picture such as acute adenitis, tuberculous or syphilitic adenitis, Hodgkin's disease, acute or chronic lymphatic or myelogenous leucemia, aplastic anemia, purpura hemorrhagica, agranulocytic angina or Vincent's angina, has shown an increase in heterophil agglutinin titer.

In view of these findings it seems justifiable to accept the test for heterophil agglutinins for sheep cells as a valuable diagnostic procedure in differentiating infectious mononucleosis from a number of clinical conditions of a far more serious nature.

Cases presenting a suggestive clinical and blood picture whose blood serum shows an agglutination for sheep cells in a dilution of at least 1 to 64 can apparently safely be diagnosed as infectious mononucleosis, and a favorable prognosis given.

PELLAGRA: Review of Cases With Special Reference to Gastric Secretions, Mulholland, H. B., and King, R. L. *J. A. M. A.* 101: 576, 1933.

The results of gastric analyses in 107 typical endemic cases of pellagra admitted to the University of Virginia Hospital during the past eighteen years confirm the results found by previous observers in regard to the common occurrence of achlorhydria in this disease, even after due allowance has been made for the presence of this condition in normal persons of different ages. The examination of some patients indicated that this condition might be more or less permanent (true anacidity), but in a few instances some degree of normal function returned. The assumption, however, that the presence of achlorhydria was necessarily correlated with such other manifestations as stomatitis, diarrhea, involvement of the central nervous system and anemia was not borne out by this study. There is no implication that achlorhydria is a primary or uniformly antecedent manifestation of this deficiency disease syndrome.

TUMORS, Carcinoid of the Gastrointestinal Tract, Raiford, T. S. *Am. J. Cancer* 18: 803, 1933.

Twenty-nine cases of carcinoid tumors in the gastrointestinal tract have been studied with regard to their clinical and pathological significance. Six of these were malignant and had metastasized to the regional nodes of the liver.

The origin of carcinoids has been a subject of much controversy. It is now generally conceded that they arise from the cells of Kultschitzky or the argentaffine cells occurring in the normal intestinal mucosa. The origin and function of these cells remain a matter of speculation, but they are thought to be related in some way to the chromaffin system.

The pathology of the group is characteristic. Occurring most commonly in the appendix, the carcinoids are yellow, submucous tumors which encroach upon the lumen. Next in frequency in the small intestine, they form small submucous or pedunculated nodules which are usually asymptomatic and are not recognized clinically. Rarely found in the stomach and large intestine, they are of more significance. They are larger, and metastasis occurs in a greater number of cases. They are clinically not unlike adenocarcinomas save for general symptoms of less severity.

The histology of the carcinoids is typified by groups and columns of cells surrounded by a dense stroma of hypertrophied connective tissue and smooth muscle. The cells are small and regular in size, the granular cytoplasm having an affinity for silver. The nuclei are uniform and are heavily dotted with chromatin particles.

The prognosis of the group as a whole is good. Only in the minority of cases which have metastasized is the outlook grave. Even in such an event, if the tumor is recognized clinically before metastasis has become widespread, a good result may be attained through surgical intervention.

MENINGOCOCCI, Variation in Agglutination of Stock Cultures of, Maegrath, B. G. *Brit. J. Exper. Med.* 14: 219, 1933.

Great variation in agglutination by "type" sera occurs among single colonies of stock meningococci.

Littledale (Type I) strains show a tendency to overlap into Type III to such an extent that these types appear to be approaching interchangeability.

There is no evidence of a division of group and specific antigens among single colonies derived from stock type cultures.

The so-called Types I and III of the meningococcus are in all probability not fixed types.

MENINGOCOCCI, Rough and Smooth Variants in Stock Cultures of, Maegrath, B. G. *Brit. J. Exper. Med.* 14: 227, 1933.

Certain variants of stock strains of meningococci can be detected by the characteristics of their growth on homologous immune-serum agar.

One variant develops haloes in this medium and the other does not.

Investigation of the properties of these variants has indicated that they are of "smooth" and "rough" nature respectively. This is supported by differences in growth in various media, in their fermentation and precipitin reactions and in their effects on guinea pigs.

Agglutination and absorption reactions with sera prepared from the variants do not agree with the results obtained by Enders with his "S" and "R" forms.

These variants are being further investigated.

MENINGITIS, Lactic Acid of Spinal Fluid in, De Sanctis, A. G.; Killian, J. A., and Garcia, T. Am. J. Dis. Child. 46: 239, 1933.

Lactic acid is a product of the inflammatory process, and in meningitis the lactic acid of the spinal fluid exceeds that of the blood, and is independent of it. The authors believe that variations in lactic acid of spinal fluid offer more dependable information concerning the progress of a case of meningitis than any other laboratory procedure at our disposal. Its practical use is further enhanced by the fact that within the last few years the technic of its determination has been greatly simplified and its accuracy increased.

SILICOSIS, Silicon Dioxide Content of Lungs in Health and Disease, Mc Nally, W. D. J. A. M. A. 101: 584, 1933.

From experimental observations it is concluded that the normal lung contains 1.13 mg. of silicon dioxide per gram of dried tissue.

A chemical examination of the lungs should be made in every case coming to autopsy, in which there is a history of a dusty occupation.

Any lung containing over 2 mg. of silicon dioxide per gram of dried tissue indicates undue exposure to a dusty atmosphere.

LIVER FUNCTION: Urinary Test as Index of Absorption of Gall Bladder Dye When Given Orally, Rudisill, H., and Hemingway, W. W. J. A. M. A. 101: 593, 1933.

The test, a modification of the Kendall test, has for its purpose the detection of gallbladder dye in the urine after oral administration.

To about 50 c.c. of urine from 1 to 2 gm. of stick sodium hydroxide is added. The mixture is heated moderately, to prevent spattering, in an evaporating dish. When evaporation is nearly complete, exactly 1 gm. of powdered potassium nitrate is sprinkled over the extract, and this mixture is fused at moderate heat until the carbon has all disappeared and the "melt" appears white. When the "melt" has cooled, 20 c.c. of distilled water is added, in which the "melt" readily dissolves. The solution is then filtered and the filtrate is acidified with dilute sulphuric acid until blue litmus is turned red. About 0.5 gm. of sodium nitrite is then added to the filtrate and the mixture is placed in a separatory flask. Five cubic centimeters of chloroform is added and the mixture shaken vigorously. A pink color in the chloroform layer indicates the presence of iodine.

Three arbitrary standards of absorption are described:

1. Good Absorption: This is indicated by a deep purplish pink and is the color obtained as a routine in the normal gallbladder visualization. This color can be reproduced by dissolving 5 mg. of resublimed iodine in 100 c.c. of chloroform.

2. Moderate Absorption: This is indicated by an ordinary pink and can be simulated by 2.5 mg. of resublimed iodine in 100 c.c. of chloroform. This degree has been obtained even with excellent visualization of the gallbladder in patients with poor kidney function.

3. Poor Absorption: This gives a very faint pink that is best seen against a white background, and the standard is made by dissolving 1.25 mg. of resublimed iodine in 100 c.c. of chloroform. When the absorption is poor, the examination should be repeated unless there is normal visualization of the gallbladder.

So far the only source of error encountered has been an erroneous index of the degree of absorption in patients with poor kidney function, as mentioned.

In case of nonvisualization of the gallbladder after the dye has been given by mouth, if the described test is positive there is no question of nonabsorption of the dye, and the gallbladder, liver, or duct system must be abnormal.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

Discovering Ourselves—A View of the Human Mind and How It Works*

THIS is a volume on normal and abnormal psychology written for the patient. Many such volumes have appeared in the past, most of which have been in greater or less measure infiltrated with ballyhoo. No one but a psychiatrist extremely well versed in human behavior and psychic reactions to suggestion would be qualified to write a popular volume that could be relied upon not to do almost as much harm as good. The problem is still further complicated by the need for a writer who can omit scientific verbiage, and discourse in a manner that will be intelligible to and will continue to hold the interest of the average intelligent layman.

Strecker and Appel have succeeded admirably in fulfilling these requisites. If you have been called an introvert and you want to know what it is you can find a straightforward explanation in this volume, one that will not increase your tendency to introversion but it will enable you to combat logically any morbid exaggerations that you might have in this direction. The extrovert and others with borderline psychiatric states can, indeed, understand themselves after a perusal of this volume.

It is one that can safely be recommended to the intelligent layman.

Histopathology of the Peripheral and Central Nervous Systems†

IT CANNOT be disputed that, while neuropsychiatry is truly a specialty, and an exacting one, neuropsychiatric problems are very often first encountered, although not always recognized as such, in general medical practice. Nor can it be easily gainsaid that for an understanding of the clinical phenomena in this field some grasp of neuropathology is essential.

For these reasons, and because, further, adequate discussions of neuropathology from the viewpoint of the physician at large have not been numerous, the present volume is presented.

It is divided into Part I (four chapters, 56 pages), covering diseases of the peripheral nerves; Part II (seven chapters, 131 pages), in which diseases of the spinal cord are discussed; Part III (nine chapters, 253 pages), covering diseases of the brain; and Part IV (seven chapters, 30 pages), devoted to staining methods used by the author.

It is apparent from these data that the volume is not encyclopedic, nor was it intended to be. On the contrary, there is presented a clear, well-written succinct and yet satisfactorily comprehensive survey of neuropathology which while of interest to workers in this field, should be gratefully received not only by the physician at large but also by the general pathologist. To these it should be very welcome and from them it will doubtless be accorded a hearty reception.

The illustrations, with but few exceptions, are well chosen, excellently reproduced, and informative. The format is acceptable.

This book is well fitted for a place on the doctor's shelf of reference texts.

*Discovering Ourselves. A View of the Human Mind and How It Works. By Edward A. Strecker, A.M., M.D., and Kenneth E. Appel, Ph.D., M.D. Cloth, pages 306. The Macmillan Company, New York, 1931.

†Histopathology of the Peripheral and Central Nervous Systems. By George B. Hassin, Professor of Neurology, University of Illinois. Cloth, pp. 491, 229 figures. William Wood & Co., Baltimore.

Modern Aspects of Gastroenterology*

THE purpose of this book is to present in an orderly and systematic manner the most valuable of the newer methods of investigation, diagnosis, and treatment in the field of gastroenterology.

While the viewpoint of the author naturally reflects European studies, American literature has not been neglected.

Gastrointestinal, hepatic, and pancreatic diseases are all considered in a satisfactory manner. The price of the volume seems a little high but is probably accounted for in part by the number of illustrations.

Filterable Virus Diseases in Man†

WHILE small, this volume presents a very comprehensive yet succinct survey of the present state of knowledge concerning those diseases at present regarded as caused by filterable viruses.

For those desiring a bird's-eye view of a subject still under investigation and in a state of flux, the book may be accepted as an excellent summary of the investigations in this field to date.

Manual of Veterinary Bacteriology‡

THOSE already familiar with this excellent book will not be surprised to find that it has reached a second edition. To those to whom it comes as a new book, it will be found an authoritative and comprehensive reference work of value, not only to the veterinary, but to the laboratory worker at large. Indeed, considering the number and importance of the diseases which may be transferred from animals to man, this volume may well be read by the physician with profit.

It can be highly recommended as an excellent and standard reference text.

*Modern Aspects of Gastroenterology. By M. A. Arafa, Medical Assistant to Guy's Hospital, London. Cloth, pp. 374, 32 plates, William Wood & Co., Baltimore.

EDITORIAL

Hyperinsulinism

ALTHOUGH it has been about twenty years since the development of reliable clinical methods for blood sugar determination, the recognition of the etiology of occasional abnormally low blood sugars has been a development of the postinsulin era. Hypoglycemia due to hyperinsulinism is often but not invariably a constant laboratory finding in the individual case. It is accompanied by certain symptoms which we are accustomed to consider as rather neurotic; nervousness, periods of weakness, abnormal sweating, tachycardia, sinking spells, and occasionally even unconsciousness. One has the feeling that if blood sugar determinations were made more frequently and more carefully on the hyposthenic nervous individual with symptoms such as these, grades of hyperinsulinism would be recognized more frequently. Such a discovery would be a great boon to this large group of sufferers. Unfortunately, however, this has not so far been a very common finding even in the type of individual men-

tioned. John¹ remarks on the apparent relative rareness so far of true hyperinsulinism stating that no one physician sees a score of such patients a year. At the same time it is highly desirable to recognize those cases which one does see.

The logical procedure in the treatment of individuals with symptoms associated with abnormally low blood sugar would appear to be the administration of sugar. This is the procedure which is usually followed, although failures have been reported by this method, probably due to the fact that the feeding of large quantities of carbohydrates stimulates the insulogenic function, thereby creating a vicious circle. The next therapeutic development appears to have been rather more successful and consists in the restriction of carbohydrates to a comfortable minimum with the addition of a reasonable abundance of fats, designed to delay the entrance of carbohydrate into the circulation, thereby avoiding overstimulation of the islets.

Partial resection of the pancreas for hyperinsulinism is a possibility and might appear as logical as subtotal thyroidectomy were it not for the tremendous operative risk and the probability that the remaining tissue would undergo rapid hyperplasia, reproducing the original state. Such operations have been done but the end-results have not yet been observed.

Henry J. John reports an entirely new therapeutic procedure, one which at first glance probably appears quite illogical but which on more detailed study gives promise of being the most logical procedure recommended so far. This briefly is the administration of insulin in hyperinsulinism. He reports its use in only one case but in this case the results were almost spectacular.¹ The single case is reported, with the idea in mind that not many cases of hyperinsulinism are seen, and that it is well therefore to report the results so that others may try the procedure in their occasional cases.

In the particular case reported John places the threshold at which insulin output is stimulated, as 200 mg. per 100 c.c., blood sugar. If the patient's digestive glycemia exceeds 200 the pancreas is stimulated to pour out insulin. If the glycemic level can be kept below 200 the pancreas will not be stimulated. The procedure therefore consists in giving insulin (ten units in this case) *after* meals, and before the peak of the blood sugar curve has been reached. This exogenous insulin starts the curve on its downward trend before it has reached 200. In this way the pancreas is kept at rest. In spite of the fact that the patient already had a hyperinsulinism, the only single time at which she experienced hypoglycemic symptoms during the period of treatment was on one occasion when by mistake she took her insulin before her meal instead of after her meal.

The blood sugar level or threshold below which hypoglycemic symptoms appeared was 70. The administration of a standard meal containing 100 grams of carbohydrates, and without the use of exogenous insulin was followed by a digestion glycemia exceeding 200. This was followed by a fall to 40 mg. per 100 c.c., well below the threshold for hypoglycemic symptoms. The interpretation was that the digestion glycemia of 230 stimulated the pancreas which put out a superabundance of insulin with a resulting hypoglycemia, sufficient to produce symptoms.

On the same diet, with insulin administered after the meal, the peak of the curve was reached at about 160, not high enough to stimulate the pancreatic tissues, and there was no subsequent hypoglycemic trough and no reaction.

During the two months in which the patient was receiving insulin, ten units after meals, she remained entirely symptom-free and gained 17 pounds. The dosage was then gradually reduced and later discontinued. One month later, at the time of the report, clinical improvement had continued without interruption.

Functional hyperinsulinism may result either from overaction of the islands of Langerhans or from some defect in the nerve control mechanism. Organic hyperinsulinism may accompany carcinoma or adenoma of the islands. Neither carbohydrate feeding nor the feeding of fat and carbohydrate has been of benefit in hypoglycemia due to hyperinsulinism from adenoma of the island. John points out that in individuals with hyperinsulinism it is important to differentiate functional disease from neoplasm of the pancreas. Often this can only be finally done following laparotomy. He suggests that on theoretical considerations the response described in his case report would not occur in individuals with organic pathology in the pancreas. In such case, the therapeutic procedure described might be developed into a therapeutic test for differentiation between functional and organic hyperinsulinism.

To Stimulate Original Research Work on Goiter

The American Association for the Study of Goiter, for the fifth time, offers Three Hundred Dollars (\$300.00) as a first award, and two honorable mentions for the best essays based upon original research work on any phase of goiter presented at their annual meeting in Cleveland, Ohio, June 7th, 8th, and 9th, 1934. It is hoped this will stimulate valuable research work, especially in regard to the basic cause of goiter.

Competing manuscripts must be in English, and submitted to the Corresponding Secretary, J. R. Yung, M.D., 670 Cherry St., Terre Haute, Ind., U. S. A., not later than April 1, 1934. Manuscripts received after this date will be held for the next year or returned at the author's request.

The First Award of the Memphis, Tenn., 1933 meeting was given Anne B. Heyman, A.B., M.S., University of Michigan, Ann Arbor, Mich., "The Bacteriology of Goiter and the Production of Thyroid Hyperplasia in Rabbits on a Special Diet."

Honorable mentions were awarded J. Lerman, M.D., and W. T. Salter, M.D., Huntington Memorial Hospital, Boston, Mass., "The Calorigenic Action of Thyroid and Some of Its Active Constituents," Prof. Dr. Stefan Konsuloff, Sofia, Bulgaria, "Experimental Studies on Etiology of Goiter."

CLINICAL AND EXPERIMENTAL

A STUDY OF THE GRANULAR AND FLOCCULAR TYPES OF AGGLUTINATION WITH *B. TYPHOSUS**†

RUTH GILBERT, M.D., MARION B. COLEMAN, B.S., AND ALICE B. LAVIANO, M.S.,
ALBANY, N. Y.

ALTHOUGH the agglutination test with *B. typhosus* is among the oldest and most universal of laboratory procedures for demonstrating evidence of infectious disease, a standardized technic which meets all needs has still to be devised. The inadequacies of the classical microscopic test are obvious. The use of living culture introduces a variable which can be controlled only within relatively wide limits. Moreover, recent investigation indicates that an analysis of certain of the agglutinative properties demonstrable with killed suspensions may furnish information of greater diagnostic significance than can be secured from the results of a single test with a living culture.

Two types of agglutinative properties in serum were demonstrated in 1903 by Smith and Reagh¹ while they were working with motile and nonmotile strains of the hog cholera bacillus. In performing agglutination tests with serum produced with the motile form, they observed a "fluffy precipitate" of the homologous strain and a "granular precipitate" of the nonmotile form which occurred only in relatively high concentrations of the serum, while both strains were agglutinated in a granular manner and to practically the same degree in serum produced with the nonmotile form. Hence, they concluded that the flagella stimulated the production of one type of agglutinative property and the body of the microorganism stimulated the production of another type. Weil

and Felix,² in 1917, reported differences in the character of agglutination obtained with *B. proteus* X 19 in sera from animals artificially immunized with this microorganism and sera from patients having typhus fever. Similarly, they were able to distinguish two types of agglutination obtained with cultures from "Hauch" and "ohne Hauch" colonies of *B. proteus* X 19; hence, they used the initials "H" and "O," respectively, for designating these two types of colony. These letters were later applied to the character of the agglutination obtained with the respective cultures and to properties in sera giving rise to the two forms of reaction. These types of clumping have also been designated as coarse and fine, and as large and small. The terms "floccular" and "granular" describe so well the character of the clumping and correspond so closely to the original terminology employed by Smith and Reagh¹ that their exclusive use seems desirable, not only for purposes of clarity and uniformity, but also in recognition of the priority of these authors' observations. The observations of Weil and Felix² and those of later investigators, notably Büchner and Zorn,³ indicate that the properties in sera which give rise to the granular type of agglutination are heat-labile, while those inducing floccular agglutination are relatively heat-stable. On the other hand, the corresponding properties in the bacteria are found to behave in an exactly opposite manner, the former being less sensitive to heat than the latter. Further studies, especially those of Weil and Felix^{4, 5} and of Weil, Felix and Mitzenmacher,⁶ demonstrated similar properties in typhoid bacilli and other microorganisms of enteric disease. Certain species, particularly *B. typhosus* and *B. enteritidis* Gärtner, were shown to have a common factor demonstrated by a granular type of agglutination, while the floccular agglutination was thought to indicate a species-specific reaction. Felix,⁷ in 1924, reported that the granular or group-agglutinative property may appear in the sera of typhoid fever patients earlier in the disease than the floccular or specific property and indicates a favorable prognosis. In this investigation, Felix employed living cultures, i.e., one strain of *B. typhosus* particularly rich in the group factor, a second showing both factors in a normal manner, and a strain of *B. enteritidis* Gärtner as a control for the granular type of agglutination.

Felix and Olitzki,⁸ in 1928, studied the characteristics of killed suspensions of *B. typhosus* and related microorganisms and reported that low concentrations of phenol and formalin definitely inhibited the granular but not the floccular type of agglutination. On the other hand, they found suspensions treated with alcohol by the method of Bien and Sontag⁹ satisfactory for demonstrating the former but not the latter type of agglutination. The observations of these workers indicate that a reaction with a formalin- or phenol-treated suspension of typhoid bacilli furnishes evidence that the patient has typhoid fever, that he has had such an illness in the past, or that he has been inoculated with typhoid vaccine, while a reaction with a suspension treated with alcohol indicates that the patient has an infection due either to the species of bacteria used in the test or to one which is allied to it. Burnet,¹⁰ in 1924, studying a limited number of cases, confirmed the observations of Felix with respect to the sera of typhoid fever patients and of persons who had received typhoid vaccine. Verzáz,¹¹ in 1924, reported the alcohol-treated suspensions of *B. typhosus* and related micro-

organisms to be more sensitive in agglutination tests than those treated with phenol. Gardner¹² and Whitehead¹³ agree in general with the findings of Felix and his coworkers, but believe that agglutination with the alcohol-treated antigen may often be demonstrated, in low dilutions at least, in the sera of persons who have received typhoid vaccine and in those of certain normal individuals as well. Felix¹⁴ reports that floccular agglutination does not occur in normal serum, whereas the granular type of agglutinative property may be demonstrated in dilutions as high as 1:100. Craigie,¹⁵ who made an exhaustive study of flagellar and somatic suspensions of the typhoid bacillus, confirms the conclusions of previous investigators that two types of agglutinative property exist, one acting on the flagella and the other on the somata. He also demonstrated very clearly that differences in the macroscopic appearance of the granular and floccular types of agglutination are associated with morphologic properties. A recent report by Eldering and Larkum,¹⁶ indicates that they have found the employment of two antigens of practical value in the examination of sera for evidence of typhoid fever.

For several years, we have hoped to be able to use killed microorganisms in the agglutination test for evidence of typhoid fever. In 1922, Gilbert and Moore¹⁷ reported failure to obtain satisfactory results with formalinized cultures of *B. typhosus* in microscopic agglutination tests. Subsequently, an extensive study of formalin-treated suspensions in macroscopic tests demonstrated that occasionally the sera from patients with typhoid fever which react in the test with living culture do not agglutinate such antigens. Most encouraging results, however, have been obtained in a series of macroscopic tests in which, in addition to a suspension of microorganisms killed with formalin, one treated with alcohol, as outlined by Bien,¹⁸ has been employed. A strain (No. 305) of *B. typhosus* isolated in October, 1929, from a specimen of feces received from a typhoid carrier was found to be suitable for the preparation of these antigens; a nonmotile variant has proved especially satisfactory for that treated with alcohol. Three other strains of *B. typhosus* which have been maintained for a number of years in the bacterial collection, No. 21 Bender, No. 62 Rawlins, and No. 176 Pfeiffer, were found unsuitable for the preparation of the alcohol-treated suspension.

Our experience has indicated that both types of antigen remain satisfactory for at least six months.

TECHNIC USED IN THE MACROSCOPIC AGGLUTINATION TEST

Before the antigens are prepared, the cultures are plated to insure the use of strains which have little, if any, tendency to develop "rough" colonies. Should such colonies be found, "smooth" colonies are fished and replated, a process which may need to be repeated several times. The culture for the formalin-treated antigen should be actively motile.

Formalin-Treated Antigen.—The twenty-four-hour growth from beef-in-fusion agar in a pint Blake bottle is suspended in from 20 to 30 c.c. of 0.85 per cent salt solution containing 0.2 per cent formalin. After seventy-two hours in the refrigerator, tests for bacterial growth are made and, if necessary, more

formalinized salt solution is added. After the microorganisms have been killed, the turbidity is adjusted to correspond to barium sulphate standard No. 3¹⁰ by the addition of salt solution containing 0.2 per cent formalin, and the agglutinability of the suspension is tested.

*Alcohol-Treated Antigen.*¹¹—The twenty-four-hour growth from beef-in-fusion agar in a pint Blake bottle is suspended in 10 c.c. of 0.85 per cent salt solution containing 0.5 per cent phenol. The growth from several bottles is combined and one-half the volume of absolute alcohol or a proportional amount of 95 per cent alcohol is added slowly, while the suspension is constantly stirred. It is then allowed to remain at a temperature of from 35 to 37° C. for about eighteen hours after which the supernatant fluid is decanted and tested for bacterial growth and agglutinability. After determination of the dilution necessary to secure a density equivalent to that of barium sulphate standard No. 3, sufficient alcohol is added to the concentrated suspension to give 2.5 per cent in the diluted antigen, which should contain not more than 0.04 per cent phenol.

Equal amounts (0.3 c.c.) of the suspensions, diluted to correspond in density with barium sulphate standard No. 3, and serum dilutions of 1 to 10, 20, 40, 80, and 160 are combined and incubated at from 50 to 55° C. for from eighteen to twenty hours. Clear supernatant fluid and, after gentle shaking, clumps which are definitely discernible to the unaided eye constitute a characteristic reaction. Vigorous shaking should be avoided since clumps of the floccular type are easily dispersed.

TECHNIC USED IN THE MICROSCOPIC AGGLUTINATION TEST

A two- to four-hour culture in bile peptone solution¹² is employed, the density of which is approximately one-half that of barium sulphate standard No. 1.¹⁰ One loopful of each of the serum dilutions used in the macroscopic test is combined with one loopful of culture on cover slips, which are inverted over vaseline-ringed hollow-ground slides. The tests are incubated for one hour at from 35 to 37° C. and the reactions read with a microscope, either a No. 6 or a No. 7 objective being used. Almost complete loss of motility and clumping of the majority of the microorganisms is regarded as characteristic agglutination.

It has been customary to consider of diagnostic significance definite agglutination reactions in the 1:40 dilution in the microscopic test and only those in the 1:80 or higher dilution in the macroscopic test.

Since this study was undertaken, approximately 4,000 sera have been examined. As the use of the various antigens was not begun simultaneously, the number of sera tested with each differs. The specimens have been divided into six groups, according to the clinical data which accompanied them. In the determination of the average agglutination titers, reactions in dilutions higher than 1:320 have not been considered. Only the granular type of agglutination has been observed with the alcohol-treated suspension. Usually the suspension treated with formalin has reacted in a floccular manner, but occasionally, especially in sera from patients having infections with organisms of the paratyphoid enteritidis group, granular clumping has also been noted.

In the first series, in Chart 1, which represents either clinical or bacteriologically proved cases of typhoid fever, the average titer with the alcohol-treated

antigen is appreciably higher than that with the other two. Of 287 sera tested with all three antigens, 259, or 90 per cent, gave reactions considered of diagnostic significance with the alcohol-treated suspension, and 252, or 87 per cent, with the living culture, while only 220, or 76 per cent, definitely agglutinated the formalin-treated antigen. Twenty-one gave no more than a partial reaction with any of the antigens, but of these, 9 were collected within the first week of illness, while in one instance the duration of illness could not be determined. Two of those giving little or no agglutination, which were collected during relapses from two to two and one-half months after the onset of illness, seem worthy of note. *B. typhosus* was isolated from the clot of one and in both instances blood specimens submitted within the first three weeks after onset gave definite agglutination. One of these cases proved fatal.

CHART 1. AVERAGE AGGLUTINATION TITERS WITH *B. TYPHOSUS*.

The reactions obtained in infections with microorganisms of the paratyphoid-enteritidis group, although only sixteen cases were studied, correspond to the findings reported. The average titer with the alcohol-treated suspension is more than three times that with the formalin-treated antigen. Five sera from two cases of paratyphoid fever are not included in this group because the patients had had typhoid vaccine. The average titer of these sera with the formalin-treated antigen was only slightly lower than that with the alcohol-treated suspension.

The remainder of the specimens were from patients who were not reported to be suffering from enteric disease at the time of the examination. The fact that only partial reactions were obtained in four sera from three of ten typhoid carriers, substantiates previous observations²¹ that the blood of these individuals

does not always give the characteristic agglutination reaction with typhoid bacilli. The floccular agglutinative properties were stronger with the specimens in this group, whereas in Group 4, which includes sera from 78 individuals who had previously had enteric disease but had not become carriers, the average agglutination titer was low and approximately the same with the three antigens tested. Eighty-five sera from 68 individuals who had had vaccine were tested with both antigens, and 24, or 28 per cent, gave reactions in higher dilutions with that treated with formalin. On the other hand, 16, or 18 per cent, agglutinated the alcohol-treated suspension in higher dilutions. In the remaining 45 sera, agglutination either failed to occur or was obtained in the same dilution with both antigens. Very interesting results were obtained with the serum from a woman who stated that she had not had enteric disease, but had received typhoid vaccine one month previously. The formalin-treated antigen was agglutinated in a 1:1,280 dilution, while a partial reaction with the antigen treated with alcohol occurred in a 1:20 dilution only.

The sixth group represents specimens from persons having infections other than enteric diseases, mostly undulant fever, and only those are included which have given some degree of agglutination with one or more of the antigens. Only seven of 197 sera tested with the alcohol-treated suspension and three of 146 tested with the formalin-treated suspension gave definite agglutination, while in the microscopic test, significant reactions were obtained in 42 of 173 sera tested by this method. Over 500 sera from cases diagnosed as undulant fever, which were examined during this period, failed to agglutinate *B. typhosus*. In a previous study,²² specimens from a considerable number of patients with a febrile disease other than typhoid fever were found to agglutinate the living culture of *B. typhosus* in the microscopic test.

Of the 4,000 sera examined, 106, with which reactions of diagnostic significance were obtained with one or more of the antigens, could not be included in any of the groups, or were accompanied by insufficient information to permit classification. Only 15 of these 106 specimens, however, agglutinated the formalin-treated suspension and only 24 the alcohol-treated suspension, whereas 92 of them reacted with the living culture.

SUMMARY AND CONCLUSIONS

Our study of a series of 4,000 sera has shown that the employment of macroscopic tests with two killed suspensions of typhoid bacilli, one to demonstrate the floccular or species-specific, and the other, the granular or group-agglutinative properties, usually furnishes information of greater diagnostic significance than does the microscopic test with living culture. These findings are in general accord with the results reported by other workers. Apparently, agglutination in a 1:80 or higher dilution with an alcohol-treated suspension usually indicates that the patient has typhoid fever or an infection incited by a species allied to *B. typhosus*, while a similar reaction with a formalin-treated suspension suggests one of three alternatives, that the patient has typhoid fever, has had the disease in the past, or has received typhoid vaccine. Both the granular and floccular types of agglutination have seldom been observed in high dilutions of sera other than those from typhoid fever patients.

A STUDY OF QUINIDIN EFFECTS ON AMBULATORY PATIENTS WITH AURICULAR FIBRILLATION*

LAURENCE E. HINES, B.S., M.D., AND CHAUNCEY C. MAHER, B.S., M.D.,
CHICAGO, ILL.

THE value of quinidin therapy for ambulatory patients who have auricular fibrillation deserves wider recognition. Statistical surveys on the value of quinidin are devoted almost exclusively to usage of large doses on hospitalized patients. Weisman,[†] however, has pointed out recently the safety and effectiveness of the drug for the ambulatory patient. This study, completed before Weisman's work was published, was made to see if small doses had a substantial effect in converting auricular fibrillation to a sinus mechanism. Twenty-eight ambulatory patients who attended the cardiac out-patient clinic of Northwestern University were the subjects. They received quinidin sulphate in divided doses which totaled no more than 12 gr. (0.8 gm.) daily. Digitalis was also used in most cases simultaneously. Twelve or 44 per cent were restored to sinus mechanism. This result compares favorably with the reports of others who have employed large doses. To our knowledge no patient was harmed by the drug.

[†]Weisman, S. A.: Auricular Fibrillation (Ambulatory Treatment with Quinidin). Arch. Int. Med. 49: 723, 1932.

An analysis of Tables I and II reveals similar age and similar duration of fibrillation in the restored and nonrestored groups. A larger proportion of restorations occurred in patients with arteriosclerosis as the etiologic factor. Table I shows that 7 of the 12 restored cases had taken quinidin for two months or longer before restoration was effected. From the well-known fact that quinidin is quickly and totally excreted, it is difficult to explain this apparent cumulative effect. Nor can the short period of the slowing of the auricular oscillation rate,* which occurred in this series, throw any light on

the mechanism. It therefore seems important to emphasize the value of continuing the administration of small nontoxic doses of quinidin for long periods of time.

SUMMARY

Small doses of quinidin sulphate are capable of establishing a sinus mechanism in a substantial percentage of patients with auricular fibrillation. There is relatively little danger in employing small doses for ambulatory patients. In some patients the drug was not effective until it had been taken for many weeks. Digitalis was used simultaneously and apparently did not interfere with the quinidin action. Small doses of quinidin were capable of slowing the auricular oscillation rate.

*The oscillation rate of auricle was obtained from needle electrodes on the anterior chest wall on 10 patients before and at 15-minute intervals after taking 3 grains quinidin. Seven of 10 showed definite slowing of auricular rate.

THE TREATMENT OF IRRITABLE COLON WITH SODIUM RICINOLEATE*†

GEORGE N. BURGER, M.D., CINCINNATI, OHIO

LARSON¹ showed that bacterial toxins could be neutralized by sodium ricinoleate in vitro. Later Dorst demonstrated that certain of the intestinal flora to which patients were highly sensitized could be detoxified in vitro and Morris and Dorst^{2, 3, 4} conceived the idea that these toxins might also be neutralized in vivo. They treated cases of irritable colon (mucous colitis) with daily doses of castor oil and later with sodium ricinoleate in gelatin capsules (soricin), obtaining very encouraging results.

They found that their patients were nearly all sensitive to autogenous vaccines made from the so-called "normal flora" of the intestinal tract, according to the method of Wherry.⁵ They also found that these vaccines could be detoxified with sodium ricinoleate, so that at least three times as much could be given without undue reaction. Detoxification did not weaken the antigenic powers. They demonstrated that, by giving these patients sodium ricinoleate orally, the skin sensitivity to heat-killed bacterial vaccines was diminished.

The purpose of this paper is to determine the effects of soricin on the symptoms and skin sensitivity to autogenous stool vaccines in cases of irritable colon. The patients were selected in the Out-Patient Dispensary and all attempts made to rule out coexisting disease, particularly intraabdominal. A diagnosis of irritable colon (or mucous colitis) was based on the accepted criteria of a history of abdominal pain, distention, constipation, a passage of excess flatus, borborygmus, nervousness, often the presence of mucus in the stools, the presence of a palpable and tender colon, and x-ray evidence of spasm.

Cultures of the stools of each patient were made. The individual strains of organisms were isolated and suspended in salt solution. They were then killed by heating to 56° for one hour. One minim of each suspension was injected intradermally and the local reaction observed twenty-four hours later. Treatment with soricin was then instituted for various periods of time.

The doses varied from 5 to 30 gr. 4 times daily. Soricin was well tolerated by a great majority of the patients. The few complaints made dealt with the large size of the capsules, occasional "sour belching," and a slight burning sensation in the epigastrium. The capsules were administered before meals and at bedtime.

*From the Department of Internal Medicine, University of Cincinnati.

Received for publication, December 26, 1932.

†This work was made possible through a grant by the Wm. S. Merrell Company, Cincinnati, Ohio.

After a period of treatment, generally of two to three months' duration, the skin tests were repeated with the original suspension of organisms. Age did not diminish the intensity of the reaction to the vaccine, as was determined by comparing the effects of a newly made autogenous vaccine with a preparation a few months old, containing the same strains of organisms.

CASE 1.—A white man, aged twenty-seven, single. The patient was first seen on April 4, 1932, complaining of gas on the stomach and pain in the abdomen. During the four weeks before admission he had noticed a dull aching pain localized below the xiphoid process, coming on three or four hours after eating and lasting until he would take soda or food. Belching gave temporary relief. He had a similar attack one year previously, lasting four weeks. He was frequently constipated.

There was localized tenderness in the epigastrium just below the xiphoid process. The abdominal findings were not otherwise remarkable. A gastric analysis following ingestion of an Ewald meal revealed free HCl 77, total acids 102. The gallbladder visualized normally. Gastrointestinal x-ray studies showed spasm of the transverse and descending colon with mucus present in the latter. He was given soricin, grains 10, four times a day. Three weeks later this was increased to 20 gr. and continued until June 9, 1932.

The appetite increased, the amount of belching and flatus were definitely diminished. The pain was very much lessened and disappeared entirely in six weeks. The constipation was relieved by liquid petrolatum. He still complained of nervousness. There was no change in weight.

The organisms recovered from the stools and results obtained were as follows:

VACCINES	MAY 23, 1932	JUNE 28, 1932
1. Hemolytic bacillus coli	3.5 x 6 cm.	negative
2. Nonhemolytic bacillus coli	negative	negative
3. <i>Streptococcus viridans</i>	1.5 x 2 cm.	negative
4. <i>Streptococcus hemolyticus</i>	negative	negative
5. <i>Staphylococcus albus</i>	negative	negative

CASE 2.—A white man, aged forty-four, single, vocation electrician. The patient was first seen in October, 1929, complaining of abdominal discomfort, fullness and belching about one to two hours after meals and constipation for a period of ten years. He also complained of nervousness. His appetite was fair. There was some palpitation of the heart occasionally after meals.

Physical examination revealed tenderness on deep pressure to the right of the midline in the epigastrium and to the right of the umbilicus. The liver was felt 2 fingerbreadths below the right costal margin. Gastrointestinal x-ray series indicated the presence of mucus in the colon. Gastric analysis after ingestion of an Ewald meal revealed free HCl 35, total 59. The patient was placed on a smooth diet with bromide, belladonna, and cascara and obtained great relief from the above symptoms until April 4, 1930. He was not seen again until Dec. 2, 1930. He felt well until two months before that time, when his former symptoms returned and the presence of mucus was noticed in the stools. Physical examination showed no changes except an occasional premature ventricular contraction. The same treatment was started again, but he failed to improve. On Jan. 8, 1932, he was placed on soricin, 5 gr. 4 times a day and bromides, belladonna, and soda after each meal. From that time until May 18, 1932, his medications were changed so that for two or three weeks he would receive only soricin, 10 gr. 4 times a day, then only bromide, belladonna, and soda for a similar period, then both together. He received almost complete relief from epigastric pain and belching, and the amount of flatus was reduced while taking soricin alone. Constipation was not relieved except when taking some laxative and mucus was present in the stools from time to time. This patient had frequent head colds during the treatment and found his symptoms aggravated each time.

Organisms isolated from the stools were made into vaccines and the patient was skin-tested with each vaccine. The organisms recovered and the results obtained were as follows:

VACCINES	APRIL 17, 1932	JUNE 27, 1932
1. <i>Bacillus coli</i>	3.5 x 5 cm.	1.5 x 1.5 cm.
2. Hemolytic streptococcus	negative	negative
3. <i>Streptococcus viridans</i>	negative	negative

CASE 3.—A white man, aged forty, married, vocation, motorman. The patient was first seen on Dec. 8, 1931, with the following complaints, which he said had been present for five years: Constipation, passage of much flatus, some bloating and belching. The stools were hard and lumpy, but contained no mucus. He complained of much nervousness and frequent headaches. He came to the clinic because he thought he had cancer.

Physical examination revealed dental caries. There was slight thyroid enlargement with normal blood pressure and pulse rate. The abdomen was negative. Gastrointestinal series showed only spasticity of the descending colon with the presence of mucus. Gastric analysis after ingestion of an Ewald meal revealed free HCl 22, total 38. The patient was placed on tincture of hyoscyamus and sodium bromide and tincture of belladonna, liquid petrolatum and a smooth diet. He felt quite well for two weeks on the above regime. He was then given soricin, 5 gr. 4 times a day with no other medication. The dose of soricin was gradually increased to 10 gr. 15 gr., and 20 gr. 4 times a day. This treatment was continued until June 15, 1932. The effect of soricin upon his symptoms may be expressed as follows: There was no change in the amount of belching, he did not complain of pain at any time, and there was no change in the amount of flatus. He still complained of constipation unless liquid petrolatum was taken regularly. No mucus was seen at any time. Nervousness was somewhat lessened, and he found that he could eat some foods without discomfort which previously he could not tolerate. Organisms isolated from the stool were made into vaccines and the patient was skin tested with each vaccine.

VACCINES	MAR. 18, 1932	MAY 23, 1932
1. Gram-negative bacillus (not an acid producer)	11.5 x 17 cm.	8 x 11 cm.
2. Colon bacillus	11.5 x 17 cm.	5.5 x 6.5 cm.
3. Staphylococcus	negative	2.5 x 3.5 cm.

Twenty-four hours after the injection of the vaccines on Mar. 18, 1932, the reacting areas in Nos. 1 and 2 were red, swollen, with increased local heat. There were 2 red streaks running up the inner aspect of the arm toward the axilla, and there was tenderness in the axilla. The patient had a temperature of 100.5° F. and complained of a headache and back-ache and general malaise. It was one week before the reactions disappeared from his arm. At the second test the areas of redness were very definite, but there was no generalized reaction.

CASE 4.—A white man, aged thirty-five, vocation, policeman. The patient was admitted to the Cincinnati General Hospital on Jan. 5, 1932, complaining of pain and a heavy feeling in the lower abdomen. During the past four years he had noticed a dull aching pain just below the umbilicus, occasionally radiating to the back. It was not related to meals and was not relieved by eating or drinking. At times it would become severe but never agonizing. His appetite was good, there was frequent belching, no nausea or vomiting. His bowels moved once a day, but in addition he complained of a desire to pass stools at other times without effect. He noticed mucus in his stools frequently. He complained of a tired aching feeling most of the time and of frequent "nervous spells." Three years ago his appendix was removed but very little relief from the above symptoms was obtained. The history was otherwise negative.

Physical examination: The patient was a well-developed but somewhat undernourished white man, appearing chronically ill. The abdominal examination revealed slight tenderness

just below the umbilicus. No masses or solid organs were felt. The colon was not palpable. The red blood count was 3,100,000, hemoglobin 65 per cent (Sahli). The urine was essentially normal. The gastric analysis following the ingestion of an Ewald meal revealed free HCl 6, total 21. An oatmeal gruel fractional test meal revealed normal acidity. Stool examination was essentially negative. Basal metabolic rate was -8 and -4 per cent. Gastrointestinal series showed areas of spasm in the transverse and descending colon. A barium enema showed spasticity of the terminal third of the colon and incompetence of the ileocecal valve. The patient was placed on soricin, 10 gr. 4 times a day, starting Jan. 15, 1932. One week later this was increased to 20 gr. 4 times a day and two weeks later it was increased to 30 gr. 4 times a day and that dosage continued, except as will be described later, until June 15, 1932. He obtained very little relief from his symptoms during the first three weeks, but he then was placed on tincture of hyoseyamus, sodium bromide and tincture of belladonna in addition to the soricin for a period of two months. Soricin was discontinued during the following three weeks but was started at the end of that time at the request of the patient and the two were used in combination until June 1, 1932. He found that more relief was obtained with a combination of the two than with either one alone. The results attributable to soricin were as follows: His appetite improved. Nausea occurred on several occasions whereas very little had been noticed before treatment was started. The pain was definitely lessened. His bowels moved more regularly while taking soricin. The stools were better formed but possessed a very offensive odor. There was no change in the amount of flatus. Nervousness was definitely lessened, and he found that he could tolerate foods that previously caused him discomfort. There was no change in the weight. Stool cultures were made at the beginning and the organisms recovered were made into vaccines for skin testing. The organisms recovered and the results obtained were as follows:

VACCINES	MAR. 18, 1932	JUNE 6, 1932
1. Colon bacillus	7.5 x 16 cm.	6.5 x 7.5 cm.
2. Gram-negative bacillus (without formation of acids)	7.5 x 16 cm.	5. x 5.5 cm.
3. Streptococcus	negative	negative

Twenty-four hours after the injection of the vaccines on Mar. 18, 1932, the reacting areas of Nos. 1 and 2 were red and swollen with increased local heat. Red streaks were seen running up the inner aspect of the arm toward the axilla. There was a small tender gland palpable in the axilla. He had a slight fever, complained of headache and general malaise. At the second test the areas of redness were very definite but there was no generalized reaction.

CASE 5.—A white man, aged fifty-three, married, vocation, fireman. The patient was first seen on Jan. 3, 1930, complaining of abdominal pain and diarrhea. For two years he had suffered from a gnawing and dragging type of pain over the abdomen. This was not localized and not related to meals. He often complained of headaches over the frontal region, of extreme nervousness and 2 or 3 loose stools a day. He had not noticed blood or mucus in the stools at any time. An appendectomy had been performed ten years before admission. There had been no weight loss. The examination of the abdomen revealed the colon to be palpable and acutely tender when pressure was applied over the lower third. The cecum and ascending colon were palpable. He was not seen again until two months later, at which time he complained of the same symptoms, and in addition he had noticed mucus and blood in the stools on 2 occasions. He had lost 15 pounds in weight. Abdominal examination revealed tenderness in both lower quadrants and in the epigastrium. Gastric analysis following the ingestion of an Ewald meal showed free HCl 38, total 52. Gastrointestinal series was negative, as far as the upper gastroenteric tract was concerned. A barium enema revealed spasticity of the descending colon. Proctoscopic examination showed only 1 small hemorrhoid. He was placed on a smooth (low residue) diet with bromides and belladonna after meals. He continued on this regime with some variations until Sept. 17, 1931. During that time he showed very definite improvement for a few weeks, until the excitement of a big fire or a near accident would set him back. On September 17, he stated

that his appetite was fair, there was some belching and rumbling through the intestines, some flatus and 3 or 4 loose bowel movements every day. He was quite nervous and always tired. Soricin, 5 gr. 4 times a day was given and all other medication and diet discontinued. The soricin was increased to 10 gr. 4 times a day on Oct. 16, 1931, to 15 gr. on Jan. 6, 1932, and to 30 gr. on Jan. 20, 1932, and continued at the latter dosage until April 27, 1932. The only other medication used during that time was occasionally a half grain of luminal at night. Throughout the course of soricin treatment he experienced the same tendency to improve for a time and then a setback would follow some excessive excitement or acute upper respiratory infection. The amount of belching and flatus were increased until the larger dose of soricin was given and then there was a definite decrease. The amount of distention and bloating was somewhat lessened. The number of bowel movements and character of the stools were unchanged. The abdominal pains were slightly diminished at first and after instituting a larger dose they disappeared. There was very little change in the degree of nervousness. No change in weight was found. Organisms isolated from the stools were made into vaccines and used to test the skin sensitivity. The organisms used and the results obtained were as follows:

VACCINES	SEPT. 17, 1931	DEC. 23, 1931
1. Colon bacillus	4+	11 x 5 cm.
2. <i>Staphylococcus citreus</i>	1+	negative
3. <i>Staphylococcus aureus</i>	1+	negative

The reacting area of the No. 1 on Sept. 17, 1931, was very marked, red, swollen and tender with red streaks up the inner aspect of the arm toward the axilla. No such reaction as this was obtained on Dec. 23, 1931.

CASE 6.—A white man, aged twenty-four, married, vocation, draftsman. He was first seen on Feb. 17, 1931, complaining of "indigestion." For the past three weeks he had noticed a sharp cutting or sticking pain in the left upper quadrant, radiating to the left flank. This would appear during his meals and would last from one-half to two hours. Though his appetite was good there was fear of eating, much belching and flatus, some nausea but no vomiting. His bowels moved regularly; there was no mucus in the stools. Coffee, tea, tobacco, fried and fatty foods caused him discomfort. He had complained of a similar condition one year before. He stated that he had been jaundiced eight years ago.

On examination, the abdomen was found to be below the chest level. There was tenderness in the left upper quadrant. No masses or solid organs were felt. Gastric analysis after ingestion of an Ewald meal revealed free HCl 33, total acids 50. The stomach, duodenum, and gallbladder were entirely negative. Barium enema showed a moderate amount of mucus in the upper part of the descending colon. He was placed on bromides, belladonna and hyoscyamus and a smooth diet with temporary improvement.

He was next seen in the clinic on Jan. 25, 1932, with complaints similar to those on the previous admission.

He was placed on the same regime as before for a period of two months with slight improvement. The treatment was then discontinued and the patient given soricin, 30 gr. 4 times a day. At the end of one week the dosage was cut to 15 gr. 4 times a day and continued at that dose until May 25, 1932, when it was discontinued at the patient's request. He stated that soricin caused a burning sensation in the epigastrium soon after taking it and that the belching, rumbling sounds, and amount of flatus were all increased. He felt that it also caused him to be more constipated and said he felt much better when not taking it.

Organisms were isolated from the stool and made into vaccines. The organisms recovered and the reactions obtained from skin tests were as follows:

VACCINES	APRIL 10, 1932	JUNE 28, 1932
1. Hemolytic colon bacillus	5 x 7 cm.	3 x 4 cm.
2. Nonhemolytic colon bacillus	2.5 x 3 cm.	0.8 x 1.0 cm.
3. Small gram-positive diplococcus	2.5 x 4 cm.	1 x 1.5 cm.
4. <i>Streptococcus</i>	3 x 3.5 cm.	1 x 1.2 cm.

It is interesting to note that in spite of decrease in bacterial sensitivity, no improvement of symptoms occurred. Since that time we have had other capsules prepared with a coating which does not dissolve in the stomach. Better results have been obtained in similar cases with the new capsules.

CASE 7.—A white woman, aged twenty-five, single. This patient was first seen on April 12, 1931, complaining of pain and a feeling of tightness over the abdomen, and constipation. Her appetite was good. There was much belching, some nausea, distention of the abdomen, with rumbling sounds and much flatus. The stools were hard and in small lumps containing mucus. Occasionally she would complain of diarrhea. There were frequent headaches and backaches. She had the above symptoms for over three years before admission to the clinic. One year before the appendix, right ovary, and right tube were removed.

Examination of the abdomen revealed a right rectus scar and tenderness in both lower quadrants. Pelvic examination was negative. Gastric analysis after the ingestion of an Ewald meal revealed no free HCl, total acids 6. Free HCl was present after the injection of $\frac{1}{2}$ mg. of histamine. Gastrointestinal series revealed spasticity of the colon with excess mucus in the sigmoid region.

She was placed on antispasmodics, sedatives, mild laxatives, and a smooth diet. This regime was continued for four months without any noticeable improvement. Soricin, 5 gr. 4 times daily, later increased to 10 gr. 4 times a day was given for two months without improvement. On Jan. 22, 1932, she was placed on soricin, 20 gr. 4 times a day, with liquid petrolatum as a laxative. This was increased in two weeks to 30 gr. and continued until May 18, 1932, when she had an attack of acute catarrhal jaundice. Her appetite remained good throughout. There was no reduction in the amount of belching and flatus. She complained of much abdominal distention and bloating. The gas pains were not diminished in frequency or severity. Soricin had no effect on the constipation. There appeared to be a definite lessening in the amount of mucus. There was no change in weight.

A stool culture in August, 1931, revealed an overwhelming growth of colon bacillus. This was made into a vaccine. A marked reaction was obtained on intradermal injection. Unfortunately, the vaccine was lost so that no test was made after treatment with soricin.

CASE 8.—A white male, aged thirty-two years, single. This patient was admitted to the hospital on Dec. 3, 1930, complaining of nervousness and bowel trouble. These symptoms had been present for thirteen years and during that time the patient had frequently noticed "yellow mucus clots" in the stools. He took a cathartic or an enema almost daily during that time. In 1924, a colostomy was performed and the colon irrigated because of a "mucous colitis." This gave improvement of symptoms at that time but after closure of the wound the same symptoms returned. He was quite excitable and worried a great deal about his condition.

On physical examination the abdomen was negative. Gastric analysis after the ingestion of an Ewald meal gave free HCl 38, total acids 53. Stool examination was negative for mucus, blood, and parasites. The patient was not seen again for a year and returned complaining of the same symptoms. A gastrointestinal x-ray series showed some redundancy of the hepatic flexure and spasticity of the descending colon. Gastric analysis revealed free HCl 48, total acids 70. He was placed on soricin, 5 gr. 4 times a day, until June 1, 1932. His appetite was good throughout. There was no belching, nausea, vomiting, or abdominal pain at any time. Constipation was relieved to some extent by liquid petrolatum, the soricin appearing to make him more constipated. The nervousness was somewhat lessened. There was a loss of 6 pounds in weight. Organisms cultured from the stool were made into vaccines and used to determine the skin sensitivity. The organisms recovered and results obtained were as follows:

VACCINES	MAR. 17, 1932	JUNE 28, 1932
1. Hemolytic colon bacillus	negative	negative
2. Nonhemolytic colon bacillus	5.5 x 6.5 cm.	3 x 4 cm.
3. Streptococcus	negative	negative
4. Staphylococcus	negative	negative

CASE 9.—A white man, aged forty-one years, married. The patient was first seen on Feb. 1, 1932, complaining of constipation. For the past nine years he had been troubled with constipation, passage of mucus in the stools, nausea, belching, and a dull pain under the left costal margin. There was also considerable nervousness and sweating. During the last eight weeks before admission to the clinic all of his symptoms were much intensified.

On physical examination the abdomen was tender in both lower quadrants. The descending colon was palpable and tender. Gastric analysis following the ingestion of an Ewald meal revealed no free HCl. Following an injection of $\frac{1}{2}$ mg. of histamine the free HCl was 62.0. Blood Wassermann was negative. A gastrointestinal x-ray series showed narrowing of the descending colon with absence of the haustra. A barium enema revealed spasticity of the distal third of the colon. The gallbladder visualized normally. A proctoscopic examination revealed only external and internal hemorrhoids. On Feb. 12, 1932, he was placed on bromides, hyoseyamus, belladonna, and soda with liquid petrolatum as a laxative. This regime was continued until April 8, 1932, without noticeable improvement. Soricin, 10 gr. 4 times a day was then added to the above medication, and he continued with that regime until May 27, 1932.

The appetite was unchanged. Belching was lessened but he complained of belching after taking the soricin, stating that the gas had a bad odor. There was definite reduction in the severity of the abdominal pain. There was some reduction in the amount of mucus. Constipation was relieved by liquid petrolatum. He still complained of much nervousness. There was no change in weight.

Organisms isolated from the stool were incorporated into vaccines and used to test the skin sensitivity. The organisms recovered and the results obtained were as follows:

VACCINES	JUNE 4, 1932	JUNE 28, 1932
1. Hemolytic colon bacillus	2.5 x 3.5 cm.	negative
2. Nonhemolytic colon bacillus	2.5 x 3.5 cm.	1.5 x 2 cm.
3. Streptococcus	negative	negative

CASE 10.—A white man, aged twenty-seven, single. This patient was first seen in March, 1929, complaining of pain in the abdomen. This was of a dull aching character located in the right upper and lower quadrants, appearing about an hour and a half after each meal. It was relieved slightly by soda and completely by a bowel movement. The pain was first noticed two years before admission. He was habitually constipated and had noticed mucus in the stools for several years. He had lost 17 pounds in weight.

The physical examination was essentially negative throughout. A gastrointestinal x-ray series was negative. The gallbladder visualized faintly after the oral and intravenous administration of iodeikon. On May 31, 1929, a cholecystectomy and appendectomy were performed following an acute attack of pain in the right upper quadrant. A chronic cholecystitis without stones was found at operation; the appendix was normal.

He was not seen again until Jan. 16, 1931, at which time he complained of the same symptoms as before operation. A gastric analysis after the ingestion of an Ewald meal revealed free HCl 48, total acids 70. A gastrointestinal x-ray series showed only hyperperistalsis. He complained of a dull pain in the right half of the abdomen, much belching and flatus, constipation with the passage of mucus in the stools, and nervousness. Various types of treatment were tried without results. In December, 1931, a series of elimination diets was used to determine the presence of food allergy with negative results. On Jan. 28, 1932, he was placed on soricin, 15 gr. 4 times a day and liquid petrolatum. In two weeks the soricin was increased to 30 gr. 4 times a day and maintained at that dosage until June 1, 1932, with the exception of ten days during May when he was in the hospital for another condition.

The appetite was poor throughout, there was slight lessening in the amount of belching and flatus. The abdominal pain was diminished. No mucus was seen in the stools after treatment with soricin was started. Constipation was controlled with liquid petrolatum. The nervousness was definitely lessened. During the ten days he was in the hospital and not receiving soricin, he stated that his symptoms were much increased in severity.

Stood cultures were made and used to test the skin sensitivity. The organisms used and results obtained were as follows:

VACCINES	MAR. 23, 1932	JUNE 6, 1932
1. <i>Bacillus mucosus</i>	4 x 5 cm.	negative
2. <i>Bacillus coli</i>	5.5 x 11 cm.	3.5 x 5.5 cm.
3. <i>Staphylococcus</i>	negative	negative
4. <i>Streptococcus</i>	2 x 2 cm.	negative

The reacting areas of Nos. 1 and 2 on Mar. 23, 1932, were red, hot, and swollen, and there was pain in the corresponding axilla. No such reaction was noticed with the second test.

CASE 11.—A white man, aged forty-one, married, vocation, engineer. The patient was first seen on Nov. 24, 1931. For the past five years he had complained of a dull aching pain radiating across the lower abdomen, coming on about one-half hour after each meal and lasting a few minutes, followed by much belching. The appetite was good, there was much rumbling of the intestines. Generalized abdominal soreness and constipation were present. No mucus or blood was seen in the stools. There was a history of syphilis eight years ago, for which he had received active treatment.

Physical examination: On physical examination there was abdominal tenderness, and the descending colon and sigmoid were palpable and tender. X-ray examination revealed moderate spasm of the transverse and descending colon. Gastric analysis following ingestion of an Ewald meal gave free HCl 20, total acid 36.

He was placed on a smooth diet of Alvarez, liquid petrolatum and tincture of belladonna for one month without noticeable improvement. On Dec. 30, 1931, soricin, 5 gr. 4 times a day, was started, all other medications being discontinued. The soricin was increased to 10 gr., then 20 gr., then 30 gr. 4 times a day, allowing two weeks to elapse between each increase, and the latter dosage continued until May 25, 1932. Liquid petrolatum was given as a laxative. Pain was much reduced after the first two weeks' treatment with soricin and was practically absent until May 5, 1932. Since then, it has been present at intervals, though of little consequence. The amount of belching was definitely lessened for four months and then returned. There was some diminution in the amount of flatus. Soricin had no effect on the constipation. His appetite remained the same throughout, but there was a loss of 12 pounds in weight.

Organisms isolated from the patient's stool were made into vaccines and the patient was skin tested. The organisms recovered and results obtained were as follows:

VACCINES	APR. 20, 1932	JUNE 8, 1932
1. <i>Bacillus coli</i>	3.5 x 4 cm.	4 x 4 cm.
2. <i>Staphylococcus albus</i>	4.5 x 5 cm.	4 x 4.5 cm.
3. <i>Streptococcus</i>	negative	negative

There was no apparent change in the reactions to the vaccines after treatment with soricin for a period of approximately five months.

CASE 12.—A white man, aged twenty-eight, single. The patient was first seen on Mar. 14, 1932, complaining of pains in the abdomen of two months' duration. They were cramp-like in character and at first confined to the epigastrium. Later they began to localize in the right upper quadrant. For two days they were accompanied by nausea and vomiting and aching over the entire body. At times there was some radiation to the right shoulder blade. His appetite was good. There was some fullness after eating during the past three or four months. Tarry foods and fried foods caused discomfort. He has been constipated since the onset of this illness. There has been a loss of 15 to 20 pounds in weight.

On physical examination there was increased resistance over the right half of the abdomen but no tenderness. Gastric analysis after the ingestion of an Ewald meal revealed free HCl 47, total acid 62. Gastrointestinal x-ray studies showed irritability of the duodenum and slight downward displacement of the hepatic flexure of the colon. The gall-

bladder visualized normally. The patient was placed on a bland diet and hyoseyamus and bromides with liquid petrolatum for the constipation. He continued on this regime for five weeks without noticeable improvement. At this time the above medication was discontinued except for the petrolatum, and he was given soricin, 10 gr. 4 times a day. This was increased to 15 gr. and then to 20 gr. 4 times a day. The belching was definitely lessened and he had relief from nausea. There was a marked diminution in the abdominal pain.

The organisms cultured from the stools used and results obtained were as follows:

VACCINES	MAY 28, 1932
1. Hemolytic bacillus coli	3.5 x 6.5 cm.
2. Nonhemolytic bacillus coli	negative
3. <i>Staphylococcus albus</i>	negative

The patient did not return to the clinic for a second determination of sensitivity.

SUMMARY

Twelve patients exhibiting the symptoms which are attributed usually to an irritable colon have been treated with sodium ricinoleate. Prior to initiation of this treatment, these patients had failed to respond to a bland diet and antispasmodics. It is to be noted that the cases reported by Dorst and Morris⁴ had all been under treatment for a period of six months or longer. Some of the inconclusive results obtained with certain of the cases included in this series are reported after only three months of treatment and would probably respond to persistent therapy. The general results may be outlined as follow:

There was diminution of the pain and belching in the majority of the cases. The amount of flatus was diminished in five. As has been previously shown, constipation was not affected. Mucus in the stools was appreciably lessened or disappeared in 50 per cent of those who showed this symptom. It is important to note that those patients who did not show clinical improvement in the treatment with soricin had, with one exception, definite gastric symptoms following the ingestion of the drug. This demonstrates the necessity for having more adequate enteric coating, since the sodium ricinoleate, if liberated in the stomach and acted upon by gastric secretions, gives rise to distressing symptoms.

The skin sensitivity to organisms from the intestinal flora was reduced materially in 9 out of 10 cases. In two cases it was impossible to obtain sensitivity records at the end of treatment.

CONCLUSIONS

1. It is felt that soricin is of definite benefit in the treatment of irritable colon.
2. There is a decrease in the skin sensitivity to bacterial vaccines following treatment with soricin.

This tends to support the theory of Dorst and Morris, that soricin neutralizes bacterial toxins in vivo.

THE EFFECT OF SALYRGAN AND X-RAY ON THE RATE OF DISAPPEARANCE OF THROMBOPHLEBITIC EDEMA*

L. M. ZIMMERMAN, M.D., J. T. GAULT, M.D., S. S. HALPERN, M.D., AND
G. DE TAKATS, M.D., CHICAGO, ILL.

IN A PREVIOUS publication,¹ we reported a method for producing edema in the hind legs of experimental animals comparable to that seen in man following deep thrombophlebitis. Chemical study of the edema fluid revealed a rather high total protein content, the values ranging from 1.25 to 2.34 per cent. It was indicated that this accumulation of protein-rich fluid in the tissue spaces might be a factor in the perpetuation of postphlebitic indurations.

In possession of a method to produce such an edema, it was possible to evaluate the effect of measures which might hasten the disappearance of the acute edema in order to prevent chronicity. Consequently, the disappearance rate of experimentally produced edema in untreated animals was compared with that in dogs given a mercurial diuretic or x-ray exposure. In the first series of experiments, salyrgan was injected to determine the possibilities of mobilizing the edema fluid by this method.² The effect of x-ray was studied because of the excellent results reported from more or less empirical clinical use of such treatment.³

METHODS OF EXPERIMENTATION AND RESULTS

Edema was produced in the leg of the dog by the method previously described, namely, the injection of a concentrated tissue extract (Fibrogen, Merrell) peripherally into the femoral vein. This results in extensive peripheral, intravascular thrombosis, and massive edema of the extremity. The dosage of fibrogen varied from $\frac{1}{2}$ to 1 c.c. and the degree of edema was usually roughly parallel to the quantity of fibrogen injected. Careful measurements of the circumferences of the limbs were made before and at varying intervals after the injections. Readings were taken at four levels: through the middle of the thigh, the popliteal fossa, the middle of the leg, and the foot. Subtracting the dimensions before injection from those after it, gave a measure of the increase in circumference due to edema. Because the variations in

*From the Peripheral Circulatory Clinic of the Department of Surgery, and the Laboratory of Surgical Research, Northwestern University Medical School.
Received for publication, January 23, 1933.

diameter at the thigh and knee greatly exceeded those of the leg and foot, a sum of the four differences, rather than an average, was taken as an index of the amount of edema. The measurements were almost entirely made by the same person, who often was not informed which of the animals were controls, and which experimental. Comparison of the circumferences of the two hind legs of the same animal revealed the margin of error in the measurements to be very small.

CONTROLS

In a series of twenty animals, edema was produced by the method described, and measurements taken at intervals over a period of two weeks. The results are shown in Chart 1. The heavy line represents the average curve in this series illustrating the rate of disappearance of edema in untreated animals. In all other respects these dogs were kept under the same conditions as were the ones in the following groups.

Chart 1.—The normal rate of disappearance of experimentally produced edema. The heavy line represents an average curve of increase and decrease of a hind limb in the untreated animal.

SALYRGAN EXPERIMENTS

In this series of twenty animals edema was produced in exactly the same way as above. At varying intervals after the edema reached its height, salyrgan, in doses of 1 c.c., was injected intravenously into the opposite extremity. In some experiments the injection of salyrgan was repeated. Salyrgan was used alone, without ammonium chloride or other acidifying agent. The results of these experiments are seen in Chart 2. The arrows indicate the time at which the salyrgan was given. The heavy black line represents the composite curve for this series of experiments. It will be seen from these curves that a rapid diminution in the circumferences of the edematous limbs occurred immediately following the salyrgan injection. It is also seen that repetition of the injection usually failed to produce a second sharp reduction in the degree of edema. The disappearance curve of the salyrgan treated animals is super-

imposed upon that of the controls in Chart 4. In this figure the average maximum circumference increase of each series represents 100 per cent, and the curve shows the percentage daily decrease in the respective groups. From this it will be seen that the greatest acceleration of disappearance time following salyrgan administration occurred during the first few days, after which the two curves run an almost parallel course.

It must be stated that no attempt was made to regulate the fluid intake of the experimental animals in this group, because no such restriction had been made in the control series. It is quite likely that, following the diuresis and consequent dehydration which resulted from the salyrgan injection, the animals consumed large quantities of water, and thus, in a measure, replaced the fluids lost. It seems reasonable to suppose that, had the fluid intake been restricted, as has been done in the case of human beings subjected to diuresis for the purpose of mobilizing excessive tissue fluid,² the rate of disappearance of the

Chart 2.—The rate of disappearance in experimentally produced edema, when salyrgan was injected at the height of the edema. The arrows indicate the injections of salyrgan. The heavy line represents the composite curve for this series. It will be seen, that the injection of salyrgan is followed by a rapid diminution in the circumferences of the edematous limbs. The second injection does not seem to be as efficient as the first.

edema would have been more rapid. These experiments at least serve to indicate that diuresis produced by the administration of mercurial diuretics is capable of mobilizing edema fluid from the extremities of animals in which experimental postphlebitic edema had been produced.

X-RAY EXPERIMENTS

The therapeutic use of x-ray has recently been advocated for the treatment of early edemas of postphlebitic origin, notably by Halban, of Vienna.³ Excellent results are claimed for this treatment. A series of experiments was performed to determine the relative effect of x-ray upon the rate of disappearance of postphlebitic edema in the laboratory animal. Edema was produced as in the other series, and at the height of the edema, the limbs were exposed

to x-ray in doses varying from 100 to 400 r. Measurements were made of the circumferences before and after irradiation, and the results plotted on Chart 3. From these curves it may be seen that a definite diminution in the edema oc-

Chart 3.—The rate of disappearance of experimentally produced edema following exposure to roentgen ray. The heavy line represents the average curve. The exposure was not always given at the height of edema.

Chart 4.—Composite graph of the three series of experiments. The straight line represents the normal rate of disappearance of edema. The interrupted line shows the disappearance of edema in animals treated with salyrgan. The interrupted line with short and long dots illustrates the diminution of edema following exposure to roentgen ray. The diminution of edema is calculated as a percentage decrease from the height of edema, the maximum increase of each series being 100 per cent. The curve for the x-ray animals coincides very closely with the curve of the animals treated with salyrgan. Both of those curves dip more rapidly than the control curve.

curring immediately following the x-ray exposure. This was occasionally followed by a slight secondary increase. In these animals, as in the others mentioned, no attempt was made to limit the fluid and salt intake. In Chart 4 are

seen the superimposed disappearance curves of all three groups, shown in percentual decrease, rather than in units of measure. The curve for the x-ray animals coincides very closely with that for the salyrgan treated ones. Both of these revealed more rapid disappearance than in the controls.

DISCUSSION

An early disappearance or diminution of the acute thrombophlebitic edema is obviously desirable, if permanent tissue changes are to be prevented or minimized. The response of such an edema to salyrgan, a mercurial diuretic, offers additional evidence of the extrarenal action of this drug. Its clinical use, combined with maximal elevation of the limb and restriction of fluid and salt intake, and followed by gradual exercise and massage, has given gratifying results.² The attempt to diminish pain and edema of the limb with x-ray has a purely empirical basis, and our preliminary results would indicate that further work on optimal dosage, filtration and time interval between treatments, is justifiable. The mechanism of its action is obscure, and one can only speculate as to whether it exerts an influence upon the lymphatic flow, or causes a breaking down of lymphocytes and leucocytes with the liberation of proteolytic enzymes and digestion of the protein-rich exudate to a more absorbable form, or results in an ionization of the tissue fluids, or systemically affects fluid mobilization. A more exact knowledge of the effects of roentgen radiation upon normal tissues must be available⁴ before an analysis of effects in pathologic conditions can be undertaken. Possibly several of the above mentioned factors are involved in the more rapid disappearance of an acute lymphangitis or periphlebitis such as we have been able to observe clinically.⁵ One of us has observed beneficial effects in the treatment of latent infections in varicose veins by means of x-ray.⁶ Further clinical and experimental studies are under way to determine the value, limitations and possible dangers of x-ray treatment in acute thrombophlebitis.

SUMMARY

Acute thrombophlebitic edema has been produced in dogs by the injection of a concentrated tissue extract into the femoral vein, and the normal rate of disappearance of the fluid has been determined in a control series of twenty animals. In a second series of twenty dogs, edema was produced in the same manner. After the edema had reached its height, salyrgan, in doses of 1 c.c., was injected intravenously. A rapid diminution of the edema followed, which definitely exceeded the normal rate of disappearance. In a third series of twelve dogs, the edematous limbs were treated with x-ray. The curve of disappearance of the edema in this group was similar to that in the salyrgan treated animals. A possible interpretation and the clinical application of these findings has been briefly discussed.

We wish to express our sincere gratitude to Dr. Earl R. Crowder of the Department of Radiology, Northwestern University Medical School, who gave the roentgen treatments and offered many valuable suggestions during the course of experiments.

A COMPARATIVE STUDY OF CERTAIN XANTHINE DIURETICS*

A. RICHARD BLISS, JR.,† PH.D., M.D., LL.D., MEMPHIS, TENN., AND
R. W. MORRISON, PH.G., B.S., M.S., COLUMBIA, S. C.

INTRODUCTION

CAFFEINE, theophylline, and theobromine have been made the subjects of extensive studies by many investigators, but no reliable quantitative clinical experiments concerning the comparative diuretic effects of the various xanthine derivatives in graduated doses have been reported. With the exception of one quantitative report in German,¹ there are no published reports of experimental work on laboratory animals with the newer theobromine and theophylline derivatives administered in graduated doses. The conflicting statements in the literature, and numerous inquiries concerning the diuretic powers of the newer derivatives of the methylxanthines prompted these investigations of theophylline calcium salicylate (phyllicin), theobromine calcium salicylate (theocalcin), theophylline sodium acetate (theocin soluble), theobromine sodium salicylate (diuretin), theophylline, and theobromine.

When the studies were begun, the primary objects were to determine what influences these agents, in graduated doses, have on diuresis, and to establish relatively safe maximum doses, so far as determinable effects on the gastrointestinal tract and on the kidneys are concerned. During the course of the work several additional factors presented themselves, the chief one being the influence exerted by these agents on the excretion of uric acid. However, during these studies no attempts were made to discover how these drugs actually increase the uric acid content of the urine, or by what mechanism they influence diuresis,² controversial points in the literature.

The consensus of opinion appears to be that, although xanthine possesses little diuretic power, certain derivatives containing the xanthine nucleus are among the most powerful diuretic drugs. Underhill and Paek³ state that caffeine, theobromine, and theophylline are without doubt the peers of drug

*From the Division of Pharmacology, College of Medicine, University of Tennessee, and the Department of Pharmacology, University of South Carolina.

diuretics for man, and that rabbits likewise are quite responsive to the diuretic influences of these compounds. These investigators found that intravenous injections of the foregoing xanthine derivatives do not increase the volume of urine output. Of the dimethylxanthines, theophylline and theobromine are the more active, while caffeine is the most effective of the trimethylxanthines. Some investigators consider theobromine to be more reliable and less prone to produce disagreeable nervous reactions, while others claim it is apt to prove irritating to the kidneys. Theophylline is credited by many with being a more prompt diuretic, and its diuretic action is supposedly of shorter duration. However, this drug is said to be more irritating to the kidneys and the gastrointestinal tract.

Caffeine, theophylline, and theobromine may fail to promote diuresis if there is not an excess of water in the tissues, as with rabbits which have been kept on a dry diet for a long period of time. These drugs, apparently, hasten the excretion of excess water.⁴ On the other hand it has been found that caffeine may fail to increase diuresis even when water is at the disposal of the animal. Schroeder,⁵ in 1886, demonstrated that caffeine invariably acts as a diuretic in rabbits if the nerves supplying the kidneys are first sectioned, or if paraldehyde or chloral hydrate are administered first to the animals, measures thought to prevent an interfering vasomotor stimulation. In the dog, diuresis is always obtained if the kidneys are denervated first or the vasomotors paralyzed, and section of the vagus nerves results in increased diuresis or induces it when absent. These observations have led to the conclusion that the vagus nerves carry inhibitory fibers to the secretory cells of the dog's kidney, and that caffeine stimulates these fibers.⁶

Wallace and Pellini⁷ showed that theophylline, theobromine, caffeine, and "diuretin" not only failed to produce a diuretic action on dogs which had been kept on a fixed food and water intake, but actually demonstrated a decided decrease in the daily output of urine which often amounted to 50 per cent of the normal volume. They found also that the sodium chloride content was diminished. These workers suggested that there is a shift of water and sodium chloride from the circulating blood to the tissues, and that caffeine and its allies bring this about through the production of a dilatation and an increased permeability of the capillaries in the splanchnic organs and muscles, these effects overshadowing the kidney action in animals which are in water balance. The diuretic effects, then, appear when there is an excess of water in the body, or when the tissues give off some of their stored water. Widmer⁸ claimed that the efficiency of caffeine as a diuretic is proportional to the amount of body fluid.

Most writers state that the effects of theobromine on the kidneys are practically identical with those of caffeine. Solis-Cohen and Githens⁹ claim that theobromine differs from caffeine in not stimulating the vasomotor and the inhibitory secretory nerves of the kidneys, and that it consequently produces diuresis constantly in dogs and in rabbits. Sasaki¹⁰ demonstrated that the continued administration of theobromine increased water excretion in rabbits only when these animals were kept on a wet diet; but that chloride excretion is increased

also on a dry diet, i.e., independently of a diuretic action. Hellin and Spiro¹¹ found that caffeine is effective in pure tubular nephritis, but that it fails in glomerular and general nephritis. They reported that theophylline and theobromine are more effective. Pearce, Hill and Eisenbrey,¹² and Schlayer and Hedinger¹³ confirmed these observations. Many consider these findings as important evidence that the diuretic effect of caffeine is exerted on the glomerular circulation and filtration, and not on the tubular epithelium. Solis-Cohen and Githens¹⁴ state that when albumin is present, the total amount is generally not increased by the ingestion of caffeine, so that the percentage is diminished because of the increased output of water. These writers state further that occasionally the total amount of albumin may be increased. Sollmann¹⁵ states that caffeine may increase the albumin in nephritis. According to Vinci¹⁶ large doses of caffeine (40 mg. per kilo), long continued especially, produce definite nephritic changes; that dogs are more susceptible than rabbits; but that no lesions have been observed following doses of from 5 to 10 mg. per kilo in man.

Sollmann and McComb¹⁷ state that caffeine in ordinary doses does not appear to produce any demonstrable injury even in nephritic subjects, but that in larger doses it may increase albuminuria. They condemn the continuous use of theophylline even in moderate doses. Emerson¹⁸ reported no increase in albumin in acute or chronic nephritis following the administration of theobromine. Miller¹⁹ is of the opinion that theophylline and theobromine may cause irritation of the stomach and kidneys. Pouchét and Chevalier²⁰ claim that theophylline in large doses injures both the glomerular and the tubular epithelia. Chevalier²¹ reported the presence of toxic impurities in commercial samples of theobromine. Vieth and Leube¹ determined the most effective daily doses of theobromine, "diuretin," "theocalcin," "phylllein," etc., in rabbits. They concluded that of the acid groups introduced in position one of the theobromine molecule, only the acetyl group increased diuresis. Bürgi's²² assumption that the diuretic powers of the xanthine derivatives are enhanced by salts was confirmed by these investigators in their experimental work with certain salicylates. They demonstrated that the calcium salts of the xanthine derivatives may influence diuresis in rabbits if this metal is combined with salicylic acid.

Stewart²³ observed that, in man, theobromine calcium salicylate produced less gastric irritation than theophylline and theobromine sodium salicylates; and that this drug may be administered daily for months without untoward symptoms. Selig²⁴ is one of the very few writers who has reported the effect of theobromine calcium salicylate on the volume of urine excreted by man. He observed that this drug induces diuresis. Cushny²⁵ states that, when large doses of theobromine are taken for some time, it is prone to act on the stomach and cause loss of appetite and nausea; and that theophylline in a number of cases has had a deleterious action on the stomach, and has caused renal irritation and epileptiform convulsions. He states further that caffeine does not injure the kidney even in large doses and over prolonged periods, and that its administration, therefore, in renal disorders is without risk of increasing the lesions. Solis-Cohen and Githens²⁶ state that in normal men it has been found that the

average increase in the twenty-four-hour urine resulting from a single dose of 0.5 gm. of caffeine is 42 per cent; and that in rabbits this is true if the doses are below 10 mg.

The literature contains numerous reports of studies concerning the effects of ingested caffeine and other methylated xanthines on the excretion of uric acid, but the reports recorded vary widely. Some investigators state that caffeine increases the uric acid content of the urine; others have found no change in the excretion of uric acid. The weight of published evidence in the earlier literature favors the former view. In 1850 Lehmann²⁷ reported that no traces of caffeine were found in the urine after the administration of caffeine. The isolation of methylated purines from normal human urine in 1895 was followed by the reports of Albanese²⁸ that the ingestion of caffeine and of theobromine in dogs resulted in the appearance of monomethyl-xanthine in the urine. During the period 1885 to 1905 Bodzynski and Gottlieb,^{29, 30} and Krüger and Schmidt^{31, 32} obtained similar results with theobromine and with theophylline when administered to dogs or rabbits. Taylor³³ reported an increase in uric acid following the drinking of coffee. Burian and Schur³⁴ found that the administration of caffeine failed to produce any effect on the amount of uric acid in the urine. Hess and Schmoll³⁵ reported an increase in the uric acid after the drinking of coffee and tea. Haig³⁶ observed an increase in the amount of uric acid following the ingestion of coffee.

In 1916 Benedict³⁷ reported an increase in uric acid following the administration of caffeine, and Brugsch and Schittenhelm³⁸ and Mendel and Wardell³⁹ obtained similar results with caffeine, coffee and tea. These investigators believe that the increased uric acid excretion is possibly due to the demethylation and subsequent oxidation of at least a part of the ingested methylxanthines. The investigations of Mendel and Wardell showed that there is a marked increase in the excretion of uric acid following the ingestion of caffeine, coffee and tea, and that the increase is apparently proportional to the quantity of caffeine ingested. They found that the increase in the amount of uric acid excreted is equal to the quantity of uric acid which would be obtained by the demethylation and subsequent oxidation of from 10 to 15 per cent of the ingested caffeine.

Clark and deLorimer⁴⁰ found that caffeine increased the excretion of uric acid in the urine, but that the primary increase was usually followed by a decrease in the excretion; and that theobromine diminished the rate of excretion of uric acid although there was no apparent change in the rate of its formation. These investigators concluded that the increased uric acid excretion following the administration of caffeine is probably due to direct oxidation of the methylxanthines, and suggested that in a general stimulation of metabolism, the kidney cells react first to the increased endogenous uric acid causing an increased excretion, and subsequently the kidney excreting cells react to the foreign and more potent compounds, caffeine or various demethylated derivatives, resulting in a specific excretion of these substances to the partial exclusion of uric acid. Cushny⁴¹ states that the uric acid of the urine is not increased by caffeine, theobromine, or theophylline. Bastedo⁴² states that caffeine in

large doses increases metabolism; and that caffeine tends to lose its methyl groups as it passes through the organism, with the resulting formation of monomethylxanthines, xanthine and urea which are excreted in the urine. Means, Aub, and DuBois⁴³ demonstrated a definite increase in the basal metabolism in man following doses of from 0.5 to 0.7 gm. of caffeine. Myers and Wardell⁴⁴ observed an increase in the urinary uric acid after the ingestion of caffeine and theophylline, but not after theobromine. These workers found that when about 300 mg. of theophylline was administered there was an increase of 100 mg. in the uric acid excreted in the urine, a quantity which represents the transformation of 33 per cent of the theophylline ingested. Taylor and Rose⁴⁵ confirmed the conclusion of Burian and Schur⁴⁶ that part of the nitrogen of ingested purine is excreted at once as uric acid, while part meets an unknown fate. Koehler,⁴⁷ and Folin, Berglund and Derick⁴⁸ have also confirmed Burian and Schur. Mendel and Lyman⁴⁹ found that hypoxanthine ingested by man caused an excretion of 60 per cent of the equivalent amount of uric acid, while xanthine caused 50 per cent, guanine 25 per cent, and adenine 34 per cent. Rose⁵⁰ concluded that caffeine and its allies are excreted as such, without the formation of uric acid, and that it was uncertain whether they have any effect on the excretion of uric acid from other sources. Magath⁵¹ claims that the uric acid in the urine is definitely increased after the administration of caffeine.

According to Wiechowski,⁵² in dogs, the increased output of uric acid after its parenteral introduction has never been reported higher than 21 per cent. For rabbits, Burian and Schur⁴⁶ reported 16 per cent, Wiechowski⁵² 5.6 per cent, Bendix and Schittenhelm⁵³ 18 per cent, and Croftan⁵⁴ from 11 to 17 per cent.

Homer⁵⁵ found that when dogs are placed on diets which are rich in meat, appreciable amounts of uric acid were eliminated in the urine, 500 gm. of meat per day yields from 0.2 to 0.3 gm. of urinary uric acid in twenty-four hours.

Burian and Schur⁵⁶ observed an increase in the hourly excretion of uric acid in dogs which had been given uric acid intravenously, the increase being most marked during the first hour or two. Later there was a fall, and the twenty-four-hour uric acid output was not increased. These investigators explained this on the basis that the rate of the normal destruction of uric acid in the body of the dog was disturbed during diuresis, probably due to circulatory changes; and conversely not due to an increased production of uric acid.

Morris and Rees,⁵⁷ who used isotonic and hypertonic solutions of sodium chloride and sodium sulphate with rats and with rabbits, observed that strenuous diuresis increased the total uric acid output in twenty-four hours, and that, as with urea, the output of uric acid is affected by the volume of the urine excreted more than any other factor. They found no evidence of uric acid arising directly from increased kidney activity. Their first series of observations were made with rats and extended over a premedication period of three days and a two-day period following the administration of one dose of the drug, given on the fourth observation day. They found with the sodium sulphate rats an average increase in uric acid output of 59 per cent at the end of the day on which the drug had been administered, as compared with the

average of the three premedication days. The chloride content was increased also. The sodium chloride rats showed a 42 per cent gain in uric acid output. The lowest gain in both groups of animals was 2 per cent, and the highest 66 per cent. The average twenty-four-hour output of uric acid for the sodium sulphate animals was 0.87 mg. per 100 gm. of body weight, and for the sodium chloride animals 0.65 mg. Hourly collections through twenty-four hours made with a second group of rats disclosed the fact that isotonic or hypertonic sodium sulphate solutions cause a large excretion of uric acid in the first or second hour with a compensatory drop later; while the sodium chloride solutions tend toward a more even level in output. The average values obtained for the twenty-four-hour uric acid output were: (1) with sodium sulphate, 0.88 mg. per 100 gm. of body weight, and (2) with sodium chloride, 0.98 mg. If these animals are grouped according to the concentration of the ingested fluids, hypertonic solutions produce 1.01 mg., and isotonic solutions, 0.81 mg. Rats of a third series were given three doses of the drugs at two-hour intervals. The sulphate animals showed a drop in the level of uric acid excreted with each administration, whereas the chloride animals showed a tendency to maintain a more uniform excretion. However, the total six-hour excretion, when calculated on the basis of weight, was practically the same in four out of five animals. There was no significant difference in the twenty-four-hour amount, the sulphate animals giving 1.55 mg., and the chloride animals 1.44 mg. In a fourth series with rabbits observations were made at twenty-minute intervals over four hours, and two drug doses two hours apart were administered. These animals yielded results which were less uniform than the rats, but they were individually consistent. The average maximum yield with the rabbits during the first two-hour period was 13.4 mg. of uric acid per 100 c.c. (the lowest being 6.3, and the highest 18.2), as compared with an average of 8.4 mg. per 100 c.c. obtained at the end of the first twenty-minute period (the lowest, 4; the highest, 11). For the second two-hour period the average maximum yield was 12.7 mg. of uric acid per 100 c.c. (the lowest, 8.5; the highest 15.4).

EXPERIMENTAL

Drugs.—Theophylline calcium salicylate (phyllicin), theobromine calcium salicylate (theocalcin), theophylline sodium acetate (theocin soluble), theobromine sodium salicylate (diuretin), theophylline, and theobromine are the drugs studied in this investigation.

Methods.—The data were from 149 adult rabbits which were kept on a complete and balanced diet determined for the individual animal. The daily water-intake was carefully controlled. The animals were housed in individual metabolic cages, and new animals were used for each dose series. The animals were observed first over a period of days to establish whether they were in a state of metabolic equilibrium. The drugs, dissolved in or mixed with definite volumes of water, were administered by stomach tube three times a day (morning, noon, and evening) over a period of four days. The observations

were continued thereafter until the daily output of urine approached that of the premedication period. Twenty-four-hour specimens of urine were collected, and the daily observations included the total volume of urine voided, the determination of the physical characteristics of the urine, the specific gravity, reaction, total solids, uric acid, urea, albumin, sugar, and microscopic examination.

Specific gravities were determined by the pycnometer method. Total solids were estimated by the coefficient of Haeser, since the quantities of urine were limited. Uric acid was determined by the method of Morris and Macleod.⁵⁵ Urea was estimated by an adaptation of the method of Folin and Wu⁵⁶ for blood analyses. Albumin was tested qualitatively by Roberts' test.⁵⁷ and, in the event a positive reaction was obtained, Esbach's method⁶¹ was employed for quantitative determinations because of the limited amounts of urine. Sugar was tested qualitatively by Benedict's test.⁶² When positive, Benedict's method⁶³ was employed for quantitative determinations. Chlorides were estimated by Whitehorn's method.⁶⁴ Allantoin determinations were attempted by Wiechowski's method,⁶⁵ but the results were unsatisfactory because of the small amounts of urine and the dilution. Each specimen was centrifugalized and the sediment was examined microscopically.

Table I shows the type of daily records which were kept for each of the 149 animals used.

OBSERVATIONS

Series I. Theophylline Calcium Salicylate.—This drug, in doses of 10, 20, 40, 50, 60, 75, 100 and 150 mg. per kilo three times a day, was administered to a series of 37 animals. The results obtained (Table II) show that with rabbits 60 mg. doses are the most efficient, if measured by increased urine output and maximum twenty-four-hour output, and that 50 mg. doses are most efficient from the standpoint of increased uric acid elimination and the duration of increased diuresis. There was no evidence of local irritation until doses of 100 mg. or more were reached, when the animals began to manifest loss of ap-

most efficient results within safe limits. Evidence of irritation was obtained with doses of 50 mg. and over. No deaths occurred until doses of 75 mg. or more were given. In cases of death, autopsy disclosed evidence of irritation of the kidneys and the gastrointestinal tract.

Series IV. Theobromine Sodium Salicylate.—Doses of 10, 30, 50, 75, and 100 mg. per kilo were used with 20 animals. The most efficient dose (Table V) was 50 mg., if determined by the increased urine output and the increase in solids eliminated. Larger doses produced a greater elimination of uric acid,

of 10 mg. as compared with those resulting from the administration of 20, 30, and 75 mg. doses are interesting. The maximum dose (75 mg.) produced death in 3 out of 4 animals, the kidneys and the gastrointestinal tract showing the effects of irritation.

Series VI. Theobromine.—Graduated doses of this drug ranging from 10 mg. to 200 mg. were given to 26 animals. The most effective safe dose from the standpoints of increased maximum output of urine, increased solids, increased elimination of uric acid, and duration of diuresis, is 40 mg. (Table VII), although 20 mg. doses produced a greater increased daily urine output. Deaths occurred with doses of 75 mg. and above, and autopsy showed renal and gastrointestinal irritation in each fatal case.

DISCUSSION

From a consideration of the foregoing data it is evident that the xanthine derivatives included in this study are capable of producing a good diuresis in rabbits, inducing increased elimination of solids and of uric acid, and maintaining a diuretic action for from two to about five and a half days after the administration of the drug is stopped. It is obvious also that in the overdosage established during this study these agents are capable of producing gastroenteritis, nephritis, and subsequent death, but that there is a fair margin of safety. The increase observed in solids was due primarily to chlorides. In general, within safe limits, it appears that when the urine output is increased, the rate of chloride excretion is accelerated until an optimum plateau is reached. Veil and Spiro⁶⁶ found that theophylline causes a prolonged fall of serum chloride even in animals whose kidneys have been removed. They conclude that theophylline affects not only the kidneys but also other parts of the vasculature, promoting the passage of chlorides from the blood into the urine and tissues.

Urine Output.—From the standpoint of increase in daily urine output theobromine calcium salicylate (61½%) and theobromine (68 per cent) produced the greater increases in dosage of 10 mg. (see Tables VIII to XII). Theophylline calcium salicylate (45 per cent) in dosage of 20 mg. produced a greater increase in diuresis than 30 mg. doses of theobromine calcium salicylate (22 per cent) and theobromine sodium salicylate (44 per cent), and 20 mg. doses of theophylline (36 per cent); although theobromine (72 per cent) in 20 mg. dosage, and theophylline sodium acetate (49 per cent), and theophylline (53½

other five drugs, theobromine sodium salicylate (26 per cent) having produced the smallest increase in this dosage. Theophylline calcium salicylate (105 per cent) in doses of 100 mg. produced an increased urine output of 105 per cent as compared with 131 per cent in the case of theophylline sodium acetate, 65 per cent in the case of theobromine, 58½ per cent in the case of theobromine calcium salicylate, and 46 per cent in the case of theobromine sodium salicylate. However, deaths occurred in the cases of theophylline sodium acetate and theobromine; theobromine sodium salicylate alone in this dosage gave no indications of renal irritation. The greater efficacy of the calcium derivatives suggests the possibility that the calcium ion enhances the diuretic properties of the xanthine with which it is associated.

Uric Acid.—As shown in the introduction, the effect of the methylated xanthines on uric acid excretion has long been a subject of controversy. The data obtained in this study make it obvious that there is a definite increase in the uric acid excreted. The administration of uric acid or nucleins is followed by an increased excretion of uric acid which is more or less closely proportional to the amount of the agent administered. Since it has been established that demethylation does occur in the body, it seems not unlikely that a part of the ingested methylated xanthines may be completely demethylated, and that resulting products may be subsequently oxidized to uric acid. Thus Burian and Schur⁶⁷ found that the uric acid injected subcutaneously into man was excreted in the urine to the extent of approximately 50 per cent, these investigators believing that the other half was broken down into unidentified products. Likewise, when hypoxanthine was ingested, about 50 per cent of its nitrogen was accounted for in the immediate increase of uric acid excreted. Although the amount of uric acid eliminated, following the ingestion of these agents, increases in a roughly uniform manner with the increase in the dose of the drug, the calcium derivatives, theophylline calcium salicylate and theobromine calcium salicylate, are exceptions in that with these agents the doses

of greater diuretic efficacy (within safe limits), as measured by the increase in urine output, produce greater uric acid excretion than larger safe doses. The action of these derivatives is apparently specifically confined to uric acid and does not involve the other nonprotein nitrogenous constituents. It is not easy to explain the mechanism by which some diuretics increase the excretion of one constituent more than that of another. The effect may be on the force with which individual substances are held in the blood and tissues, or it may be a direct effect on the tubule epithelium influencing reabsorption to a different extent.

The percentages in the tables expressing increase in the uric acid excreted may be unintentionally self-exaggerating because of the small amounts of uric acid in the urine before medication. To illustrate: In the case of one rabbit which received 20 mg. doses of theophylline calcium salicylate, the daily output of uric acid during the premedication period averaged 11.7 mg. (or 5.85 mg. per kilo of body weight), and during the medication period the average daily output rose to 31.6 mg. (or 15.8 mg. per kilo of body weight), an increase of 19.9 mg. (or 9.9 mg. per kilo of body weight). This represents an increase of 170 per cent in uric acid, although the increase was but 9.9 mg. per kilo or 0.99 mg. per 100 gm. of body weight.

In 10 mg. doses theobromine calcium salicylate (217½ per cent), theophylline sodium acetate (154 per cent), and theophylline calcium salicylate (125 per cent) produced the greater increases in uric acid eliminated. In 20 mg. doses theophylline calcium salicylate (140 per cent) induced a greater increase than theobromine (130 per cent), and theophylline (117 per cent). In doses of 30 mg. theophylline sodium acetate (189 per cent), theobromine calcium salicylate (180 per cent), theophylline (152 per cent), and theophylline calcium salicylate (140 per cent) were more effective. In 40 mg. dosage theophylline calcium salicylate produced an increase of 184 per cent and theobromine 162½ per cent; while in doses of 50 mg. theophylline calcium salicylate (395 per cent) manifested more than twice the powers of the remainder of the group with the exception of theophylline itself (222½ per cent). In this dosage theobromine sodium salicylate produced the smallest increase (158 per cent) in uric acid eliminated.

In 60 mg. doses theophylline calcium salicylate (233 per cent) effected a greater increase in uric acid elimination than theobromine (151 per cent); and in doses of 75 mg. theophylline calcium salicylate (280 per cent) again topped the list.

When the limits of safety of this group of agents as a whole were reached (doses of 100 mg. and over), theophylline calcium salicylate (537½ per cent) still exceeded all other members of the group in increasing uric acid elimination, although theobromine sodium salicylate (262 per cent) was the only member of the group which in 100 mg. doses manifested no symptoms of poisoning. However, the administration of theobromine (135 per cent) itself in dosage of 100 mg. produced death in three out of four animals.

Duration of Diuretic Action.—In 10 mg. doses theophylline manifested activity over a period of nine and one-half days; theobromine, eight and one-half

days; theophylline calcium salicylate, and theobromine calcium salicylate, seven and one-half days; theophylline sodium acetate, six and one-half days; and theobromine sodium salicylate, six days. In doses of 20 mg. and 30 mg. theobromine (eight and one-half days), theobromine sodium salicylate (eight days), theophylline (seven and two-thirds days), and theophylline calcium salicylate (seven days) produced the more prolonged action.

When doses of 40 mg. and 50 mg. were ingested, theobromine (nine and one-third days), theophylline calcium salicylate (nine days), and theobromine calcium salicylate (eight and one-half days) were the more effective members of the group.

In 60 mg. and in 75 mg. doses theophylline calcium salicylate (seven and one-half and eight and two-third days) and theobromine (seven and three-fourths and eight days) were approximately equally effective, although with the larger dosage one theobromine animal died on the second drug day.

All members of the group are prompt in action, increased diuresis starting in practically all cases on the first drug day.

Toxicity.—Theobromine sodium salicylate is the only member of the group which manifested, in the doses employed, no toxicity. However, it should be noted that in this study this drug was not administered in doses larger than 100 mg., and that theobromine itself in doses of 75 mg. produced death in one out of four animals, while with doses of 200 mg. the mortality was 100 per cent by the third or fourth drug days.

The limit of safety is reached apparently with theobromine, theobromine calcium salicylate, and theophylline when these agents are given in doses of 75 mg. per kilo three times a day. In the cases of theobromine calcium salicylate and theophylline calcium salicylate 150 mg. doses seem to be definitely toxic, although in 100 mg. doses, while showing no fatalities, both drugs produced a definite increase in the albumin in the urine.

Autopsies disclosed positive evidences of both renal and gastrointestinal irritation in all animals that died.

Relative Efficacy.—If the increase in urine output, the increase in solids eliminated, the increase in the elimination of uric acid, safety, and the duration of diuretic action, are taken into consideration (see Table XIII), theophylline calcium salicylate, in doses of from 50 to 60 mg. per kilo three times a day, is most efficacious, and theophylline itself in doses of 50 mg. stands second among the remainder of these xanthine derivatives so far as rabbits are concerned. Theobromine calcium salicylate in doses of 50 mg. stands third, close in efficacy to theophylline.

The results of these studies confirm the statements of Underhill and Pack³ that theophylline and theobromine are powerful diuretics in rabbits (as well as in man). The consensus of opinion in the literature that (1) theobromine is more reliable than theophylline; (2) that theophylline is a more prompt diuretic but shorter in action and more irritating to the kidneys and the gastrointestinal tract; (3) and that both of these xanthine derivatives are capable of producing irritation of the kidneys and the gastrointestinal tract, agrees only in part with the findings of this investigation. These studies disclosed

the facts that in rabbits (1) theobromine and theophylline and their salts are equally reliable diuretics; (2) that in both of these groups diuresis began promptly within approximately the same time (usually the first medication day), and, in the more efficacious doses, was practically of equal duration; and (3) that renal and gastrointestinal irritation is produced by practically the same dosage of the members of each of these groups (excepting "diuretin," which was not administered in doses larger than 100 mg.).

In clinical doses Stewart²³ found that theobromine calcium salicylate produced less irritation than theobromine sodium salicylate. The findings of this study show that in rabbits with doses up to and including 100 mg. theobromine sodium salicylate gave no indications of irritation, whereas theobromine calcium salicylate in doses of 100 mg. and over produced an increase in urine albumin.

Vieth's and Leube's¹ observation that calcium salts of the xanthines apparently influence diuresis in rabbits is confirmed by the results obtained in these studies.

The conclusion of Emerson¹⁸ that there is no increase in albumin after theobromine is contradicted by these findings, since theobromine in 75 mg. doses and theobromine calcium salicylate in 150 mg. doses both gave definite evidence of an increase in urinary albumin.

The observations of Bodzynski,²⁰ Gottlieb,³⁰ Krüger,²¹ Schmidt,³² Hess,³³ Schmoll,³⁵ Mendel and Wardell,³⁰ and others that there is an increase in uric acid following the ingestion of theophylline and theobromine are confirmed by this work. The conclusion of Morris and Rees²⁷ that the output of uric acid is affected by the volume of urine more than any other factor does not agree with the results obtained in these studies.

The relative toxicity of the salts as compared with the free xanthines appears to be about directly proportional to the amount of the xanthine contained therein, with the exception of theophylline sodium acetate which is as toxic as theophylline.

The authors wish to express their appreciation of the valuable assistance rendered by Pearl B. Waddell, A.B., M.D., formerly Assistant in Pharmacology, and Jessie May Gill, B.S., formerly Assistant in Pharmacology, College of Medicine, University of Tennessee, who carried out most of the routine clinical laboratory work.

EMBOLISM AND THROMBOSIS OF LARGE BRANCHES OF THE PULMONARY ARTERY IN HEART DISEASE*

LEONARD G. STEUER, M.D., CLEVELAND, OHIO

OBSTRUCTION of the pulmonary artery, like that of other vessels may occur as a result of thrombosis or embolism. The two processes having so much in common, and often so difficult to differentiate are usually considered together in discussions of this subject. Although the literature abounds with general studies on thrombosis and embolism, the relationship between pulmonary obstruction and heart disease has been somewhat neglected.

The study of the mechanism of thrombosis has been vigorously pursued and the definite answer as to how and why intravascular clotting occurs is still to be forthcoming. John Hunter¹ believed that infection of the vessel wall was responsible for thrombosis. Later, Virchow² brought forth a noninfectious process as the cause, namely, a sluggish circulation, which with other factors predisposed to the clotting. He applied the term "marantic" to thrombi of such origin. In a study of 1,000 cases of thrombosis and embolism, Rosenthal³ found the incidence highest in individuals over forty-one years of age in whom heart disease was present. The inference would be that stasis of the blood resulting from a failing myocardium is responsible for thrombus formation. Experimental work, however, has shown that stasis alone, or in association with endothelial injury will not result in thrombus formation. It appears, therefore, that

*From the Department of Medicine, Western Reserve University at City Hospital.
Received for publication, December 17, 1932.

changes in the blood itself, physical, chemical and colloidal changes, are necessary in order that thrombus formation take place.

Emboli on the other hand are usually pieces of clot which have broken off. There are in general two types of pulmonary emboli,⁴ one in which a large branch of the pulmonary artery is occluded, and the other in which smaller branches are occluded to produce either local disturbances or infarction. A large embolus may pass through the heart and lodge in the trunk of the pulmonary artery.

McCartney⁵ in his review of 73 cases of pulmonary embolism has included 16 cases of so-called medical embolism, embolism occurring in nonsurgical cases. Of these 16 cases, 6 were associated with cardiac disease. From this data it may be concluded that about 8 per cent of emboli occur in cardiac disease. All of McCartney's heart cases suffered from hypertensive disease.

In this connection the work of Haggart and Walker⁶ is of interest. Studying the effect of quantitative occlusion of the pulmonary artery they found that until from 52 per cent to 66 per cent of the pulmonary circulation is cut off, there is no significant variation in the circulatory condition of the animal. The point at which failure occurs is sharply defined, since beyond this end-point a circulatory collapse is precipitated by minute increases in pulmonary arterial obstruction, but if this is not applied, no untoward change results. This experimental evidence coincides with the clinical findings of Means and Mallory,⁷ who report a case of occlusion of the main right branch of the pulmonary artery by an organized thrombus which had been present for a period of many days or even weeks.

The present study is based upon 25 cases of frank cardiac disease, appearing on the wards of Cleveland City Hospital. All cases at autopsy had occlusion of large main branches of the pulmonary arteries. In 6 instances the pathologic diagnosis was that of pulmonary embolus.

Of the 6 cases in which the diagnosis of embolism was made there were 5 males and 1 female. The youngest was thirty-six years of age and the oldest fifty-nine years, the average age being fifty-two years. Of these, 3 cases had mitral stenosis; 1 had hypertensive heart disease; 1 had syphilitic aortitis and general paresis; 1 had coronary disease. Strikingly enough, in all cases the cardiac mechanism was normal. This is of significance, because ordinarily emboli are thought of as occurring with arrhythmias, but here none of the cases show such abnormality. In only 1 of these patients was death of the type commonly associated with pulmonary emboli. This case, one of chronic mitral and aortic disease, was found moaning while asleep. Cyanosis and dyspnea developed and death was sudden. In all the other cases death could be attributed to additional factors, the pulmonary embolus being apparently of minor consequence and occurring as a terminal event. For example, 1 case had a cerebral embolus; 1 the wet brain of general paresis; 1 coronary thrombosis; and the other 2 chronic failure of from six to twelve months in duration.

We may conclude from these cases that the typical death attributed to pulmonary embolism, the chest pain, dyspnea, cyanosis and anxiety, may be

often absent when the condition occurs in the course of heart disease. It appears that pulmonary embolism occurs so late in heart disease that it represents a terminal event.

A possible source of the embolus was found in 3 cases. Pulmonary infarcts were present in 2 instances.

In the remaining 19 cases of this study, the pathologic diagnosis was that of thrombosis. The youngest of these was thirty-five years of age and the oldest seventy-three years. There were 8 females and 11 males.

In all but 3 of these, cardiac failure was present to an obvious degree. As near as can be determined, the average time of failure was three months. Thus about 85 per cent of the cases were associated with cardiac failure extending over long periods of time.

The 3 cases which had no failure are of interest. One had coronary disease with myomalacia; another cerebral necrosis with a thrombus straddling the bifurcation of the inferior vena cava; a third had a cerebral hemorrhage.

In the cases then, in which myocardial failure was absent, other conditions were present which were sufficient to produce lethal exitus. In all instances the pulmonary thrombosis may be considered as a condition coming at the termination of an otherwise fatal disease.

In the cases of thrombosis there is again a striking paucity of cardiac arrhythmia. Only 5 of the cases, approximately 25 per cent were fibrillating, and there was 1 case of premature beats. As in the process of embolism, auricular fibrillation is not a frequent companion of thrombus formation.

Various types of cardiac disease are represented in this series. Hypertensive heart disease occurred in 13 instances, about 65 per cent. Rheumatic heart disease appeared in 1 case. Syphilitic heart disease appeared 3 times. Coronary disease was present 2 times and chronic pulmonary emphysema once. When studied with respect to the number of these diseases admitted to the hospital, it would seem that hypertensive disease is represented a little more than anticipated and rheumatic heart disease a little less. Embolism is more often associated with rheumatic disease and thrombosis with hypertensive disease.

Pulmonary infarcts were present in 13 instances, 68 per cent of the cases of pulmonary thrombosis, a much higher incidence than in cases of pulmonary emboli.

The frequency of antemortem thrombi in the right side of the heart was studied. In 7 instances there were such thrombi present. In 4 cases the thrombi were in the auricles alone; in 1 case in the right ventricle alone; in 2 cases in both auricles and ventricles.

In 3 additional cases there were thrombi in the venous system. These thrombi were found in the inferior vena cava, the right iliac vein and the gastro-epiploic vein.

The following cases are representative of this series:

L. C., a negro male, forty years of age, was admitted Apr. 19, 1932, and died Aug. 20, 1932. He had been failing for four months. His heart was enlarged, gallop rhythm. Blood pressure was 160/100. Clinical diagnosis: diffuse vascular disease, and congestive cardiac failure. Anatomic diagnosis: nephrosclerosis, cardiac hypertrophy, thrombus right pulmonary artery, thrombosis right auricle and left ventricle, chronic passive congestion, and multiple pulmonary infarcts.

E. N., a negress, thirty-six years of age, was admitted Feb. 21, 1929, and died Mar. 13, 1929. She had had shortness of breath and swelling of ankles for two weeks. On examination she had Cheyne-Stokes respiration, left-sided hemiplegia, enlarged left ventricle, with systolic murmur at apex. Blood pressure was 114/64. Clinical diagnosis: cerebral accident, and either embolism hemorrhage or thrombosis. Anatomic diagnosis: mitral stenosis, mural thrombi, right auricle and ventricle, pulmonary embolus, patent ductus arteriosus, and encephalomalacia,* right.

One of the purposes of a study of this kind is to increase diagnostic skill as a result of the classification of disease. From the diagnostic standpoint there is nothing particularly distinctive about these cases. If, in a case of cardiac disease the typical symptoms of pulmonary embolism appear, the diagnosis is simple. From the cases studied, however, it appears that this is not likely to occur. In heart disease the pulmonary emboli are usually quiescent and give little manifestation of their presence. A similar statement can be made concerning thrombi. It can be said, none the less, that in a case of prolonged cardiac failure, with repeated indication of pulmonary infarction, embolism, or thrombosis of the pulmonary vessels may be anticipated. This is in accord with the opinion expressed by Brenner⁸ who in his report of 6 cases of thrombosis of large branches of the pulmonary artery, concludes that thrombosis usually occurs after severe congestive cardiac failure has set in and produces no evident additional symptoms though it probably hastens the end.

CONCLUSIONS

1. Twenty-five cases of cardiac disease with embolism or thrombosis of the larger pulmonary arteries are reviewed.
2. Hypertensive cardiac disease is most frequently associated with pulmonary thrombosis.
3. Rheumatic heart disease is most frequently associated with embolism of the pulmonary arteries.
4. Auricular fibrillation was present in only a few cases.
5. Diagnosis of these conditions usually must be made by inference.

*This may have been due to a paradoxical embolus passing through the patent ductus arteriosus.

MULTIPLE TUMORS*†

REPORT OF A CASE

W. L. McNAMARA, M.D., HINES, ILL.

WHILE the occurrence of multiple tumors in a single individual is of no definite scientific importance at this time, their presence, nevertheless, arouses interest and never fails to invite speculation as to the reason for their existence.

Puhr, in 1926, published a study of a series of 6,718 necropsies performed during the preceding twenty-one years at the Second Budapest Pathological Institute, finding 1,559 cases of tumors. Two hundred and nineteen of these, or 14.04 per cent of the tumor cases, showed multiple growths. Puhr concludes from his assembled data that the occurrence of multiple tumors in the same individual is common enough to indicate the existence of a "tumor diathesis" either congenital or acquired. It is to be noted that in this series only five of the cases of multiple newgrowths show more than one tumor of the malignant variety.

Egli, quoted by Murray, finds multiplicity of neoplasms in the same individual in 263, or 27.3 per cent, of 966 tumor cases, which were studied during a seven-year period at the Basel Pathological Institute. In twenty of these cases, multiple malignant growths were demonstrated.

Harlitz, quoted by Murray, found 16 cases of multiple malignant growths in 524 cancer autopsies seen during the period of time from 1900 to 1915. These sixteen cases thus represented roughly 3 per cent of the total number.

Murray states that thirty-two examples of multiple malignancy were found in a series of 4,219 examinations made at the Oslo Institute for the Norwegian Cancer Committee. Thus, multiple malignancy was encountered in 1 per cent of the cases.

From a study of the reports of these authors and of various statistical studies concerning the occurrence of malignant tumors, Murray concludes that the multiplicity of neoplasms is rare, particularly the coexistence of tumors of the malignant variety. He feels that there is probably inherent in one malignant tumor a tendency to inhibit the development of other malignant tumors.

Yamakawa has reported a case of coexistent gastric cancer, lung cancer, kidney adenoma and neurofibroma of the suprarenal. Luchsinger reports coexistent canceroid of the forehead, bronchial cancer, malignant hypernephroma and osteochondroma of the lungs. Seecef found coexistent carcinoma

*From the Clinical Laboratory and Laboratory Center and Cancer Center, Edw. Hines, Jr. Hospital.

Received for publication, December 15, 1932.

†Published under R. & P. 6969 U. S. Veterans' Administration.

of the lung and carcinoma of the rectum, each producing typical metastases. Other cases of multiple tumors have been reported by Risak, Siebke, Ball and Reynolds, Perrotti, Jolkwer and others.

We wish to report a case of four different coexistent tumors found at

Fig. 1.—Sixteen mm. obj. oc. 15 \times camera 50 cm. \times 300 reduced. Penile tumor showing formation of epithelial whorl.

Fig. 2.—Eight mm. obj. oc. 15 \times camera 50 cm. \times 600 reduced. Hepatic tumor showing gradual transition from liver cords to the ill-defined tumor columns.

autopsy at the Edward Hines Jr. Hospital. This represents the only case showing multiple malignant newgrowths in a series of 364 autopsies.

CASE 1.—J. C., white male, aged sixty-two years, entered the hospital December, 1930, complaining of extreme weakness and loss of weight; a recurrence of penile growth which had occasioned a subtotal amputation about six months previously.

Family History.—Revealed nothing of interest.

Past History.—Patient denied venereal infection. In 1924 a rodent ulcer of the left jaw was removed surgically. There had been no recurrence of this tumor. In October, 1929, a lesion appeared on the foreskin of the penis which was later diagnosed as "cancer" and for which a subtotal amputation of the penis was performed in June, 1930. An ulcer on the

Fig. 3.—Four mm. obj. oc. 15 \times camera 50 cm. \times 1200 reduced. Liver tumor showing large cloudy cells forming ill-defined cords. Note the mass of pigment within space at center of cut.

Fig. 4.—Four mm. oc. 15 \times camera 50 cm. 1200 \times reduced. Liver tumor. Detail showing mitotic figure.

left cheek had been gradually enlarging over a period of ten years until at the present time it is 1.5 cm. in diameter.

Physical examination revealed an emaciated senile male who was in an extreme cachectic state. An ulcer of approximately 1.5 cm. in diameter was seen on the left cheek approximately 2 cm. below the outer canthus of the eye. A large cauliflowerlike growth involved the penoscrotal junction. The nodes of the right inguinal region were enlarged.

The other physical findings were irrelevant.

Clinical Course.—The penile tumor and regional lymph nodes were repeatedly subjected to irradiation. Despite the treatment, the condition of the patient became steadily worse and death resulted on Jan. 7, 1931.

Autopsy resulted in the following anatomic diagnoses: Epidermoid carcinoma penis

Fig. 5.—Sixteen mm. oc. 15 \times camera 50 cm. \times 200 reduced. Kidney tumor showing well-defined line of demarcation between renal tissue and atypical tubule formation of neoplasm.

Fig. 6.—Eight mm. oc. 15 \times camera 50 cm. \times 600 reduced. Details of renal tumor. The atypical tubule formation is noted.

with metastases to regional lymph nodes; adenocarcinoma liver; adenoma kidney, right; carcinoma, basal cell type, face; bronchopneumonia; arteriosclerosis, advanced, severe; nephritis, interstitial, chronic, vascular type; myocardial degeneration; chronic passive congestion of liver; atrophy spleen, senile; hypertrophy prostate, adenomatous; hyperkeratosis, senile, left face; dermatitis, senile, legs.

Description of gross appearance of organs which proved on histologic examination to be the site of distinctly different neoplasms.

1. *Penis*.—The remnant of the penis was destroyed by a fungating cauliflowerlike growth. On section this tumor had a wartlike periphery, the inner portion being pearly white and of a cartilaginous consistency. The glands of both inguinal regions were dense and fibrosed but showed no gross evidence of tumor.

2. *Liver*.—A firm, grayish white nodule 3 cm. in diameter was found on the antero-lateral margin of the dome of the right lobe elevating the capsule somewhat. Cross-section through this mass revealed a homogeneous grayish white pearly surface of almost cartilaginous consistency. It was not encapsulated.

3. *Right Kidney*.—This organ weighed 140 gm. A nodule 2 cm. in diameter was located in the middle third of the cortex and bulged beneath the capsule. Section through the nodule revealed a yellowish white, smooth, homogeneous cut surface. This tissue was found to be of a firm consistency, but was not encapsulated although the edges were well defined.

4. *Skin Lesion Noted on Face*.—A shallow ulcer 1 cm. in diameter with elevated borders

Fig. 7.—Sixteen mm. oc. 15 \times camera 50 cm. \times 300 reduced. Skin tumor. The epithelial invasion of the lower strata is noted.

of dense consistency was noted over the left molar region. The edge of the ulcer cavity was undermined. The base was filled with recent granulations. This lesion had the gross characteristics of a "rodent ulcer."

Histologic Examination of Penile Tumor.—Examination revealed a proliferation of squamous epithelium which invaded the deeper layers of tissue in long finger-like projections. The cells were well differentiated and contained much keratinization with the formation of epithelial "whorls." Mitotic figures were few in number.

Diagnosis.—Epidermoid carcinoma of penis.

Histologic Examination of Liver Tumor.—A regular epithelial cell proliferation forming ill-defined columns which closely resembled liver cords was noted. The cells were large, some being round and others elongated in shape. These cells showed a cloudy cytoplasm and a large open vesicular nucleus with a well-defined nucleolus. Mitoses were frequent. There was a definite well-marked fibrous stroma which was well vascularized. Indefinite channels, in many of which were small free masses of brown pigment, were formed between the cords of epithelial cells, probably in an ill-formed bile capillary. A gradual transition from the well-differentiated liver cell to the irregular atypical tumor cell existed without definite line of demarcation.

Diagnosis.—Adenocarcinoma of liver.

Histologic Examination of Kidney Tumor.—The epithelial proliferation tended to form columns and well-marked tubules of irregular size on well-vascularized stroma. The cells were large and oval with cloudy reticular cytoplasm. The nuclei were large and hyperchromatic and contained well-defined nucleoli. No mitotic figures were seen. The line of demarcation between the kidney parenchyma and tumor tubules was definite although the tumor was non-encapsulated. The latter lack the uniformity of true renal tubules both as to diameters and cytologic lining.

Diagnosis.—Adenoma of kidney.

Histologic Examination of Skin Lesion.—A well-marked proliferation of the lower layers of the epithelium infiltrated deeply into the submucosa. The cells were small, some round, and some oval with hyperchromatic nuclei. These cells formed masses with pseudocolumnar margins and closely resembled those seen in the basal layer of epidermis. No mitotic figures were noted.

Diagnosis.—Carcinoma, basal cell type.

SUMMARY

A case is reported in which at autopsy was demonstrated the simultaneous occurrence of four tumors, three malignant and one benign. Seven years previously the patient was operated upon for a rodent ulcer which did not recur.

CHOOSING A SERUM TEST FOR SYPHILIS*†

WILLIAM A. HINTON, M.D., BOSTON, MASS.

IN ADDITION to considerable laboratory experience with several of the numerous modifications of the Wassermann test, and with some of the so-called precipitation or flocculation tests, I have applied these serum tests to the diagnosis and management of syphilis in the clinic. It is, therefore, from a point of view which combines laboratory and clinical experience that I wish to consider the problem of choosing a serum test for syphilis.

The ideal or completely adequate test would be one which would give positive reactions in all cases of syphilis, and in no others. Thus, the first requirement for ideal adequacy would be that the test to be so sensitive as to detect the presence of syphilis from the beginning of the infection to the complete destruction of every *Treponema pallidum* in the body. According to present knowledge, no serum test can be expected to be entirely adequate in regard to this requirement because before the serum can give a positive reaction the *Treponema pallidum* must have resided in the body long enough to have evoked some sort of tissue response which directly or indirectly causes the detectable changes in the serum. Such changes rarely occur sooner than ten days after infection. Furthermore, serum tests are lacking in adequacy, in that, as yet no method has been devised which definitely indicates when the last treponeme has been destroyed. The second essential for an adequate serum test would be that it be specific in all cases. The occurrence of positive reactions with the serum of nonsyphilitic persons is obviously a serious fault.

From a practical standpoint there are certain other essentials for adequacy. The test must be dependable; its technic should be of such a nature that it can be accurately executed by the average laboratory worker, the results being consistent from day to day, and consistent with those obtained in other laboratories performing the same test. Furthermore, in addition to being sensitive, specific, and dependable, a method should be comparatively inexpensive. However accurate a new method is, it will not receive general recognition if the expense of performing the test is much greater than that of some of the excellent methods already in use. Finally, in order to survive, the method must be easy of execution, and easier still of interpretation.

Since it is inconceivable, from present knowledge, that any test could be completely adequate, one should be guided in the selection of a test for syphilis by its helpfulness to the physician.

*From the Department of Clinical Research, The Boston Dispensary, and the Wassermann Laboratory, Massachusetts Department of Public Health.
Received for publication, February 8, 1932.

†Read (by invitation) before the Laboratory Section of the American Public Health Association, Washington, D. C., October 25, 1932.

COMPLEMENT FIXATION TESTS

Since the Wassermann reaction is the oldest and most widely known test, I shall speak first of its inadequacies:

1. Lack of sensitiveness has taught able clinicians never to disregard unmistakable signs of syphilis merely on the strength of a negative Wassermann reaction. Failures of the Wassermann reaction are approximately 50 per cent in the primary stage of the disease, are few in the secondary stage, and vary between 40 and 60 per cent in the tertiary stage, depending upon treatment, duration, and so-called latency.

2. A positive Wassermann reaction is not always specific for syphilis, because certain acute respiratory infections, particularly pneumonia, and a few other conditions such as malaria and bacterial endocarditis, often cause positive reactions in individuals who are not syphilitic.

3. None of the many modifications of the Wassermann test is entirely dependable. Altogether too frequently there arises a situation in which a positive report is received from one laboratory, and a negative report from another, even though both laboratories are using the same Wassermann technic on separate samples of the same blood. Still more perplexing is such an occurrence as a report of a positive reaction in a given laboratory, followed very shortly, without any clinical reason, by a report of a negative reaction in the same laboratory.

In spite of these imperfections, we must not underestimate the immense contribution of the Wassermann reaction, for in doubling ability to detect the disease, it has, to date, I believe, done more to control syphilis than any other single factor.

FLOCCULATION TESTS

During the last ten years numerous tests have been devised for the purpose of increasing accuracy in the detection of syphilis and of more efficiently excluding it in differential diagnosis. Most of these new tests have made use of the principle, first stated in 1907 by Michaelis, and two years later affirmed by Jacobstahl, that the serum of a syphilitic person, when mixed with a suspension of suitably chosen lipoids, usually produces a change in the dispersion of the lipoids, leading to flocculation; the term "flocculation" is used rather than "precipitation" because flocculation describes a change rather than defines a mechanism, as yet not fully understood. It is not difficult to understand why so much progress has been made in the development of flocculation tests when one remembers that in order to effect a positive reaction with syphilitic serums, only the admixture of lipoids is necessary. On the other hand, the Wassermann reaction or any complement fixation test requires, in addition to the lipoids and the serum to be tested, three different reagents (amboceptor, complement, and sheep's cells), all three of which are biologic products whose respective potencies have never been controllable with certainty. It is now generally admitted that the flocculation tests are more dependable, and in my experience they have proved more specific than any of the complement fixation methods.

As a result of investigations of several flocculation methods in the laboratories under my direction, it has been possible to make the following comparable ratings in terms of adequacy, as expressed by sensitiveness and dependability. In a large group of cases studied it was found that the Eagle test possesses 72 per cent of the adequacy of the Hinton, the Kahn test 70 per cent, the Kline test from 71 to 80 per cent, and the Wassermann test from 38 to 46 per cent. The range of adequacy in the case of the Kline test has depended upon whether the antigen used was prepared in Kline's laboratory or in my own laboratory. With the former I obtained 71 per cent of adequacy, and with the latter I obtained 80 per cent of adequacy, as based on sensitiveness and dependability. With Kline's antigen which I prepared, however, the results suffered considerably in specificity, since there were several non-specific positive reactions. In the case of the Wassermann reaction, the range was greatly influenced by the type of cases, the sensitiveness being greater among the cases of syphilis from venereal disease clinics than among those of neurosyphilis from psychopathic hospitals.

It thus appears that in regard to sensitiveness and dependability there is little to choose between the Kline, the Kahn, and the Eagle tests. Accordingly, other factors must determine the choice. Each of the tests that I have mentioned presents certain difficulties. The Kahn test is admittedly difficult to read, although an unusual degree of accuracy in reading this test has been attained by those trained in Kahn's laboratory. The Kline test presents very few technical difficulties that are readily discernible; however, in our hands it has had its good and bad days. The difficulty with the Eagle test lies in its technic; in a laboratory in which a large number of tests are done, centrifuging each tube is difficult and impractical. The greatest difficulty with the Hinton test is that despite its simplicity it must be performed with exactness and precision for the best results. This can be obtained only by practice; in the hands of a serologic technician with no experience with the Hinton test, 80 to 90 per cent of adequacy can be obtained in less than a month, while the highest degree of accuracy in testing and reading usually requires experience of several months. Another practical disadvantage is the necessity of overnight incubation. These obstacles, however, I believe are outweighed by the greater sensitiveness and dependability of this test.

I feel strongly on the question of adequate sensitiveness of a test for syphilis; I have seen much suffering and great expense caused by a negative Wassermann reaction which, with absence of clinical signs, caused the physician to conclude that the disease was not present, when actually it existed in a communicable form. Thurmon's¹ figures show that during the first week after the appearance of the primary lesion, the Hinton reaction of the blood was negative in only 38 per cent of the cases studied; that in the second week of the primary lesion only 14 per cent were missed by the Hinton test, and that from the beginning to the end of the third week only 6 per cent of the cases remained negative. It is a well-known fact that in primary syphilis in which more than three weeks have elapsed since the beginning of the initial lesion, serum reactions are practically 100 per cent positive by any worth-while method.

In addition to the value which sensitiveness has for the early detection of syphilis, it has equal, if not greater, importance as an aid in the determination of cure. In the tests with which I have had experience, there has been none except the Hinton test which, in a large group of cases, was always positive whenever the spinal fluid showed a positive reaction by accepted tests.² This is of great importance to the general practitioner particularly, for it means that when the Hinton reaction of the blood is negative one will be unable, by lumbar puncture, to disclose laboratory evidence of neurosyphilis.

INTERPRETATION OF STATISTICS

In the determination of the adequacy of a test, statistics, which for the most part must serve as the guide, are often misleading. The two chief reasons for this are: (1) frequently the cases upon which figures are based are insufficiently studied clinically, and (2) the statistics are often erroneously prepared. Any such study, to be valid, must be based upon a complete as well as a careful clinical examination of each case by experts in syphilology. I would, for this reason, exclude all other than institutional cases in a statistical investigation of the adequacy of *any* serum test for syphilis. In referring to erroneously prepared statistics, I have in mind particularly those indicating the percentage of agreement between two methods. I can illustrate a frequently occurring fallacy in statistics by the following: Suppose a laboratory were to test 1,000 nonsyphilitic bloods, using two given methods, one of which was absolutely insensitive. The results would agree unless, perchance, one of the methods gave nonspecific reactions. If, using the same methods, tests are made upon 1,000 individuals, 10 of whom are definitely syphilitic, and 990 of whom are not, and one method finds the bloods of the 10 known syphilitic individuals positive, and the 990 normal persons negative its score will be 100 per cent. The method lacking sensitiveness finds not a single syphilitic's blood positive, though it finds the 990 negative; its true rating would be nil, yet, according to prevailing statistical methods, it would be computed as showing 99 per cent of agreement, a totally misleading figure. Suppose, however, that one has the bloods from 1,000 syphilitics. A given method finds 900 of these bloods positive; another test finds only 600 of these bloods positive. The accuracy of the first method is 90 per cent, whereas the accuracy of the other method is only 60 per cent. It is, therefore, manifest that in preparing statistics on the adequacy of a method, by comparison with another test, one must have, as a basic figure, the number of persons known to be infected. The efficacy of any method must be determined primarily on the basis of the number of actual syphilitic patients, and secondarily on a control group consisting of a sufficient number of nonsyphilitic persons to demonstrate that the test gives no nonspecific reactions, or, at most, only an occasional one.

FAITHFUL EXECUTION OF AN AUTHOR'S TECHNIC

Having chosen a method because of belief in its adequacy, as manifested by its sensitiveness, specificity, and dependability, it is incumbent upon the worker to execute each step of the test in the exact manner prescribed by the

author. There are several reasons for this caution, which might perhaps better be called "admonition." Before publication of his test, the author has carried on hundreds of experiments to perfect his technic. His directions and instructions are based on the technic he has found most successful, and no change should be made except on the basis of equal or more painstaking research. I recently read an abstract of an article on the Hinton test which stated that the sole advantage of the test was that it was easier to perform, but that it was no more sensitive than the Wassermann test. There was, however, a statement in the article that 0.1 c.c. and 0.3 c.c. of serum had been used in the Hinton test, instead of 0.3 c.c. and 0.5 c.c. of serum as directed. In my experience, fully 30 per cent of the specimens that give a well-marked characteristic reaction with 0.5 c.c. of serum are negative when only 0.3 c.c. is used. My selection of 0.3 c.c. and 0.5 c.c. was based on an examination of several thousands of bloods of persons who were investigated clinically as well as serologically.

Besides strict adherence to technical details, each worker must remember that as sensitiveness of a method increases there must be increasing precision in its execution. The Hinton test, which has proved, in my hands, more than twice as sensitive as the Wassermann test, is perceptibly affected by slight differences in the temperature of incubation, whereas the same temperature variations have had no discernible effect on the Wassermann test. In diluting antigen for the Wassermann test, I have not been able to discover any marked difference in the result when slight variations of the method have been made. In the Hinton test, however, in three laboratories under my direction, the slightest variations in diluting the indicator (I prefer to call it indicator rather than antigen) have caused inconsistencies in the results. Several months ago I designed a special flask³ for the purpose of diluting indicators, and as a consequence the three laboratories almost invariably obtained the same results when the same specimens of blood were tested.

I have recently simplified the technic of the Hinton test (third modification).⁴ This simplified method, which has been in operation in my laboratories for the past six months, is being maintained because it is superior in sensitiveness and specificity to my former methods. Its description, according to the statement of my students, sounds difficult and austere, but after they have actually performed the test their response is that it is very simple. The reason why the test sounds difficult is that I have made the directions as explicit as I could; each admonition represents a pitfall, the discovery of which has occupied days, weeks, months, or in some instances even years.

SUMMARY

The chief value of a serologic method of testing for syphilis lies in a high degree of sensitiveness, specificity, and dependability; the ease of execution and interpretation, as well as economy in cost, are secondary qualifications. Flocculation methods fulfill these requirements best. Of those now available, choice must be made on the basis of accurate, but not misleading; statistical

studies, rather than on simple comparisons with the Wassermann or any other test. Whatever method is chosen, best results will almost invariably follow from the closest adherence to the author's directions.

STUDIES ON HEMOLYTIC STREPTOCOCCI ISOLATED FROM HEMORRHAGIC SMALLPOX*

L. W. FISHER, LAFAYETTE, IND.

POSSIBLY no group of bacteria can claim more varied and more numerous types of pathogenic activity than the streptococci. Although these micro-organisms are easily recognized, because of their morphology, the possibilities of their unwarranted behavior are always a source of interest to the research worker in these fields.

The hemolytic streptococci are responsible for inflammatory and suppurative conditions which vary greatly in severity and effect. Such lesions range from trivial localized inflammations of transitory duration to those of great intensity, spreading rapidly to the tissue spaces by way of the blood. Exogenous infection, associated sometimes with epidemic spread, is a conspicuous feature of certain diseases due to the hemolytic streptococci, and virulent strains may produce sudden and fatal septicemia without any apparent lesion at the site of the initial infection. Following Jenner's¹ notable work on smallpox, there was a series of attempts to prove the bacterial origin of variola, and the literature on the contents of vesicles is large and embodies a variety of opinions. Many bacteria have been described in this connection, some of them new, others old and well-known forms. Among the researches in this field, we find the works of Garre,² Protopopoff,³ Waele and Sugg,⁴ Perkins and Pay,⁵ and Hines,⁶ dealing with the various phases of smallpox and their relations to the streptococci.

Because of these facts the present studies have been undertaken, not to prove the organism in question to be the etiologic factor, but rather to study its cultural, morphologic, serologic, and immunologic characteristics, and thus classify the different strains by their reactions to the several stimuli.

*Received for publication, February 16, 1933.

Submitted to the faculty of Purdue University, June, 1931, as a thesis in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

CULTURAL HISTORY

In the course of a rather severe epidemic of smallpox which occurred in Detroit several years ago (1924), the opportunity presented itself to study, culturally, fatalities, the result of hemorrhagic smallpox. The epidemic was widespread and the individuals observed were from various parts of the city. Each patient entered the hospital as a confluent type and the hemorrhagic developments appeared from four to eight days after admittance. The strains when cultured on blood agar were hemolytic, and when examined macroscopically, the colonies were similar. In all, 9 strains were isolated and for purposes of identification have been designated as "Var.," while those forms from scarlet fever, erysipelas, and puerperal septicemia have been identified by number only.

All cultures isolated from sources of fatal hemorrhagic smallpox were from adults, ranging in age from twenty-eight to forty years, none of whom gave any history of vaccination. Pure cultures were obtained in every instance although this fact is not stressed as being of significance as an etiologic factor. Strains isolated from puerperal septicemia were obtained from the blood of patients who later died. Streptococci obtained from erysipelas were in one instance (02168), a blood culture from a fatal terminus, and in the other (02005) a culture from a skin lesion. Both of these strains show high cross agglutinating titer with the Birkhaug strains. Those streptococci isolated from authenticated instances of scarlet fever were from throat cultures and both strains produce specific toxin of a high titer.

In the isolation of streptococci one requisite is that the culture medium be fresh and that its composition be such that the organism in question will grow satisfactorily. A great variety of both fluid and solid mediums have been advocated by research workers, most of them making use of tissue extracts of brain, kidney, or spleen. Previous experiments in the isolation of streptococci led to the conclusion that veal broth and the brain liver media of Hibler gave most satisfactory results. The standard veal broth was prepared, containing the aqueous extractives of 500 gm. of lean chopped veal, 5 gm. of *c. p.* sodium chloride, and 10 gm. of Witte's peptone per liter. Dextrose in the amount of 0.2 per cent was added. The final reaction was adjusted to P_H 8.0 and the broth distributed into 500 c.c. flasks, each containing 200 c.c. The tissue medium of von Hibler⁷ as modified by Goss, Barbarin and Haines⁸ was also employed in making blood cultures.

The blood was drawn at the bedside under aseptic conditions from the median basilic vein and transferred immediately into culture medium. A quantity of 2 c.c. was added to the veal infusion bouillon and a like amount to the flasks containing the Hibler medium. The seeded flasks were taken at once to the laboratory and 1 c.c. of the diluted blood added to a mixture of 5 per cent sterile rabbit blood and 2 per cent agar, thoroughly agitated and poured into sterile Petri dishes. The resulting mixture represented a 1:100 dilution of the original blood. The plates, veal bouillon, and the Hibler medium were then incubated for twenty-four hours at 37° C. after which they were examined macroscopically.

In every instance a pure culture of *Streptococcus hemolyticus* was obtained from both the fluid and solid mediums. The blood plates never showed less than 400 and in several instances the number was as large as 900 organisms per c.c., computed on the basis of the original sample. Well isolated, typical single

colonies, appearing on the blood plates, were selected and subcultures were made on blood agar slants, veal bouillon, and whole defibrinated sheep blood.

MORPHOLOGIC AND CULTURAL CHARACTERISTICS

The bacteriologic literature is crowded with classifications of organisms of every sort, based usually upon their metabolic activities, morphology, pathogenic

properties, manner of growth, and their ability to produce toxins, either soluble or insoluble. Numerous tests have been devised by thoughtful investigators to determine the type of organism under consideration. There occur, however, many criticisms of these classifications and as yet no general agreement has been reached relative to their respective values. In view of the various methods of classification and the apparent dissention among workers in this field as to their merits, it is not the intention of the author to attempt to classify the organisms

in question by any certain concise methods, but to give a true picture of the reactions on different culture mediums according to the various workers.

The growth and morphology of each strain of *Streptococcus variolae* isolated, and cultures of streptococci from scarlet fever, erysipelas, and puerperal septicemia, were carefully noted, when cultured on infusion broth and blood agar. The data which are presented in Table I seem to indicate that there is but little variation between the strains.

TABLE I

MORPHOLOGIC AND CULTURAL CHARACTERISTICS OF STREPTOCOCCI ISOLATED FROM SMALLPOX, SCARLET FEVER, ERYSIPELAS, AND PUERPERAL SEPTICEMIA

CULTURE	GROWTH		MORPHOLOGY		HEMOLYSIS	BILE SOL.
	BLOOD AGAR	BROTH	BLOOD AGAR	BROTH		
Var. 1	Small, smooth white colony	Clear, flaky sediment	Cocci in pairs and chains	Chains of 10 to 50	Wide zone	Negative
Var. 2	Small, smooth white colony	Clear, flaky sediment	Small cocci in pairs and chains	Chains of 6 to 50	Medium zone	Negative
Var. 3	Small, smooth white colony	Clear, flaky sediment	Small cocci in short chains	Chains of 10 to 50	Wide zone	Negative
Var. 5	Small, smooth blue white colony	Clear, flaky sediment	Medium cocci in short chains	Chains of 10 to 50	Wide zone	Negative
Var. 6	Small, smooth blue white colony	Clear, flaky sediment	Medium cocci in short chains	Chains of 8 to 50	Wide zone	Negative
Var. 7	Small, smooth white colony	Clear, flaky sediment	Small cocci in pairs and chains	Chains of 8 to 60	Wide zone	Negative
Var. 8	Small, smooth white colony	Clear, flaky sediment	Cocci in pairs and chains	Chains of 6 to 50	Wide zone	Negative
Var. 12	Small, smooth white colony	Clear, flaky sediment	Cocci in short chains	Chains of 10 to 50	Medium zone	Negative
Var. 14	Small, smooth opaque colony	Clear, flaky sediment	Medium cocci in short chains	Chains of 6 to 40	Wide zone	Negative
Ery. 02168	Small, smooth white colony	Semi cloudy with sediment	Small cocci in short chains	Chains of 3 to 15	Narrow zone	Negative
Ery. 02005	Small, smooth white colony	Semi cloudy with sediment	Small cocci in short chains	Chains of 6 to 20	Narrow zone	Negative
Scar. 01730	Small, smooth colony	Clear, flaky sediment	Medium cocci in chains	Chains of 6 to 30	Wide zone	Negative
Scar. 01841	Small, smooth colony	Clear, flaky sediment	Medium cocci in short chains	Chains of 6 to 22	Narrow zone	Negative
Puer. 02224	Small, smooth colony	Semi cloudy flaky sediment	Medium cocci in short chains	Chains of 6 to 30	Wide zone	Negative
Puer. 02087	Very small, smooth colony	Clear, flaky sediment	Medium cocci in short chains	Chains of 4 to 30	Wide zone	Negative

It appears from Table I that all the strains isolated from hemorrhagic smallpox were, in the main, very similar and indistinguishable culturally from other hemolytic streptococci, such as those from scarlet fever, puerperal septicemia, and erysipelas. They produce small, smooth colonies with hemolytic zones of varying diameters. Grown in veal bouillon they have a tendency to settle to the bottom in a flaky sediment.

The cells in strains 01841 and 01730, isolated from scarlet fever, were somewhat smaller than those isolated from the patients with variolae. In general, the strains from hemorrhagic smallpox produced a much wider zone of hemolysis than the others studied.

Figs. 1 to 4 show photomicrographs of 2 strains of streptococci isolated from smallpox cultured on solid medium, in bouillon, and also a direct blood smear from a rabbit.

FERMENTATION REACTIONS

Although the many authors who have carried out research on the fermentation reactions of the different streptococci are at variance in their opinions relative to the merit of this test, there is no doubt that characteristics thus established for the many strains of these organisms serve as a valuable aid in differentiating between the predominant types. Comparatively few have considered all criteria in classifying the strains studied by them. The Germans have given special attention to the morphology of the streptococci and their appearance on blood agar; the English have made an exhaustive study of the fermentation reactions of these organisms, while the Americans have divided their attention between one or the other set of characters. It is obvious that any research on the subject of the fermentation reactions of the streptococci must take into consideration certain essential precautions if reliable results are to be obtained. In these tests special care was exercised in the selection of the test substances in order that they be pure, sufficient time for the fermentation was allowed to elapse, and none of the test substances was injured by overheating.

All strains of the streptococci tested were first grown for 10 generations in veal infusion bouillon, P_H 8.0, and tested daily for purity. They were then transplanted for 3 generations on blood agar after which they were transferred to the carbohydrate medium. Double strength broth was made sugar-free in the usual manner, using *B. coli* as the fermenting agent. After complete fermentation the broth was filtered through a sterile Berkefeld filter, adjusted to P_H 8.0 and to every 200 c.c. of the sugar-free broth, 4 c.c. of Andrade's indicator, together with 4 c.c. of the test substance, was added. This was sterilized in flowing steam for twenty minutes on three successive days, cooled, and 200 c.c. of serum water (1 part horse serum to 300 parts of sterile distilled water) added under aseptic conditions. The finished carbohydrate serum broth was then tubed and incubated several days to insure sterility. Acid production caused by the fermentation of the test substance was noted by the color change and recorded. Table II shows the results of the fermentation action of the different strains of streptococci being studied.

It will be noted that with one exception all organisms isolated from smallpox are negative for lactose, while the control strains from erysipelas, scarlet

fever, and puerperal septicemia all ferment lactose. This action, together with the action on the other test substances, would place the streptococci from smallpox under the head of *Streptococcus equi*, according to Holman's classification. The six comparative strains, would according to the same scheme, fall into that group, usually referred to as *Streptococcus pyogenes*. However, a careful review of numerous authors on the subject of *Streptococcus equi* shows such a variance of opinions that one is at a loss to know the true characteristics of the organism in question. In addition, each culture was planted in litmus milk and observed during a period of two weeks. The data are presented in Table III.

TABLE III

ACTION OF THE STREPTOCOCCI ON LITMUS MILK

02087	Puer.	+	-	-

From Table III we find that those strains of streptococci isolated from smallpox show no acid production in litmus milk while the comparative strains

all show marked acid production in twenty-four hours. This reaction according to Jones⁹ and Mathers,¹⁰ is characteristic of *Streptococcus equi* but is contradicted by the work of Besson¹¹ and Bergey.¹² Such opinions make a definite classification impossible. The fact that the strains of streptococci from smallpox vary among themselves and from the strains used as controls in their ability to ferment certain differential substances and their action on litmus milk, does indicate, however, that the strains in question are different from those usually classed as *Streptococcus pyogenes*.

VIRULENCE

The most significant property possessed by certain of the streptococci is that of dissolving red blood cells. The fact that this hemolytic action is confined to certain types of streptococci and not possessed by others serves as a method of classification and to some extent, bears a definite relation to the virulence of the organism. A review of the literature including the works of Rolly,¹³ Besson,¹¹ and McLeod,¹⁴ shows a difference of opinion, relative to the direct relation between hemolysin production and virulence.

In order that the virulence of the strains be at a maximum, they were serially transferred at twenty-four-hour intervals for 10 generations in 5 per cent horse serum broth, P_H 8.0. The culture representing the tenth generation was then injected into white mice which were subsequently killed. The heart blood was then transferred into tubes of serum broth and after twenty-four-hour incubation at 37° C., a portion of the bouillon was injected into a second

mouse. This technic was repeated until the virulence of each strain was at a maximum. Table IV contains the results of these experiments.

It would appear from Table IV that no strain of the streptococci isolated from smallpox is of high virulence for mice. Only 1 strain killed in a 1:100 dilution and the remaining strains killed only in a 1:10 dilution. It is to be noted that these strains are of a relatively low virulence when compared with those killing mice in dilutions of 1:100,000.

AGGLUTINATION EXPERIMENTS

The various immunity reactions so frequently employed for diagnostic purposes, such as agglutination, complement fixation, and bacteriotropine tests, give the most convincing evidence of biologic grouping. Many strains of bacteria, although indistinguishable by cultural methods, may be divided into separate groups. In the study of the hemolytic streptococci there seems from the beginning, some basis for an immunologic grouping of these organisms.

The immune scrums used in the serologic tests were obtained by the immunization of rabbits weighing approximately 2,000 gm. Previous experience, Ferry and Fisher,¹⁵ showed that individual rabbits immunized intravenously gave less variation and more constant results than those immunized by other methods. Each animal was given 3 intravenous injections of killed germs suspended in saline, preceded by one desensitizing injection, given subcutaneously. Five days after the last injection the rabbits were bled. The first, or desensitizing injection, given subcutaneously was 0.5 c.c. followed by 1 of 1 c.c. and 2 of 2 c.c. each, given intravenously three days apart. Two rabbits were treated with each of the 15 strains of streptococci being studied, after tests for agglutinins had been made against scarlet fever streptococcus 01730, puerpural septicemia 02087, erysipelas 02168, and smallpox Var. 3 and Var. 8. No rabbit was used whose serum showed any degree of agglutination in amounts less than 1:20 dilution. The suspensions to be used as antigens were grown in 100 c.c. quantities in a 0.1 per cent glucose broth, P_H 8.0, for twenty-four hours. The cultures were then centrifugalized and the sediment washed with saline to prevent the production of agglutinins to the protein constituents of the medium. The sediment was then taken up with normal saline solution containing 0.4 per cent tricesol and standardized in such a manner as to correspond to a suspension of 1,000,000,000 organisms per c.c. as this was found to be a safe dose for rabbits and compares closely to the count of broth cultures.

Agglutination tests may meet with difficulties on account of the tendency of streptococci to form clumps. The tendency of the streptococci isolated from smallpox to show spontaneous agglutination was overcome by using care in the preparation of the organisms to be used in the agglutination reaction. The broth was made from selected meat, and in place of the usual sodium chloride a sufficient quantity of dibasic sodium phosphate mixture was added to give the desired isotonicity and P_H . The organisms were removed from the culture medium by centrifugation and washed in broth prepared in the manner previously described. They were resuspended in the same type medium in approximately the concentration that was used in the agglutination reaction. The clumps were broken down by vigorous shaking and 0.5 per cent solution of

formalin added to kill the organisms. The suspensions of the controlling strains, while showing less tendency toward spontaneous agglutination, were prepared in the same manner as were the strains isolated from smallpox.

The serums employed in the tests were made up to the various concentrations by dilution with the same broth used for suspending the bacteria. Each reaction was controlled by a series of both normal serum, and suspension in the absence of serum. Equal quantities of dilute serum and bacterial suspensions were added to each tube and placed at 37° C. for eighteen hours. If this procedure is carefully followed there is less chance of nonspecific granulation occurring. If clumping develops in the broth control or in more than the first few normal serum controls, the test must be discarded.

Homologous and cross agglutinations were run with the 9 strains of smallpox streptococci and 2 each of scarlet fever, puerperal septicemia, and erysipelas streptococci. Table V gives the highest dilution of a specific serum showing definite agglutination against its homologous and heterologous strains. The 9 strains of streptococci from smallpox did not cross agglutinate to any appreciable extent with those from scarlet fever, puerperal septicemia, or erysipelas. There was, however, cross agglutination in high dilutions between the several strains from smallpox.

COMPLEMENT FIXATION REACTIONS

The principle of complement fixation has long been utilized in bacteriologic investigations, for determination, in the serum, of specific antibodies. Although a classification of streptococci on the basis of complement fixation has not proved as valuable as agglutination tests, it has been employed by many investigators to establish a natural classification of these organisms. In these studies, homologous and cross complement fixation tests were carried out with the same cultures as those used for agglutination, with three exceptions, due to the anti-complementary action of antigens prepared from Var. 5, Var. 8, and 02005.

Antigens were prepared in the following manner: Each culture was grown for twenty-four hours on 0.2 per cent dextrose sheep serum agar, P_H 8.0, in Roux flasks. The growth was washed off in 15 c.c. of normal saline solution and made up to 50 c.c. per flask. Each suspension was shaken for fifteen minutes and the remaining clumps allowed to settle for several hours. The supernatant fluid, containing the organisms was then decanted off, heated to 56° C. for one hour and killed with 0.5 per cent phenol. Stable antigens of all cultures, with the noted exceptions, were prepared by this method. They were nonhemolytic in quantities of 0.5 c.c. of a 1:5 dilution, nonanticomplementary in workable units, and comparatively high in antigenic value. The amount of antigen used was from 2 to 4 times the antigenic unit, usually 4 times, depending on the anti-complementary unit.

The tests were made by an adaptation of the Kolmer¹⁶ technic, the quantitative determinations being carried out with decreasing amounts of inactivated immune serum. Referring to Table VI one finds the results of the complement fixation studies. The average of the highest dilutions of the two rabbits immunized with a specific strain is taken as an index in each instance. A comparison of these results shows that they run about parallel with those of the agglutination tests.

TOXIN PRODUCTION

During the last decade an exhaustive study of the streptococci and their soluble toxins has occupied a major portion of the time of many workers. In spite of extensive research upon the nature of the poisons produced by these microorganisms, our knowledge is still incomplete. The grave systemic symptoms often accompanying streptococcus lesions argue strongly for the production, by these organisms, of a powerful, diffusable, toxic substance. The toxins produced by the streptococci differ from most other true bacterial toxins in being thermostable. Many preparations will withstand boiling, and some may be boiled for an hour without entirely losing their capacity for skin reactions. Inasmuch as laboratory animals are not highly susceptible to the toxin, its standardization is limited at present to tests on susceptible human beings.

The question as to whether the streptococci isolated from hemorrhagic smallpox would produce a soluble toxin, thus presented itself as worthy of consideration. Was the fatal outcome of these cases due to a bacteremia, to a toxemia, or to a combination of the two? The toxin production was carried out on especially prepared medium. Veal infusion agar was made from carefully selected meat, and great care was used to remove all fat from the broth. One per cent Witte peptone, 0.85 per cent sodium chloride, c. p. were used and the broth titrated to P_H 7.8. The medium was placed in 200 c.c. quantities and seeded with the various strains of streptococci isolated from smallpox and with one strain each of scarlet fever, erysipelas, and puerperal septicemia. Incubation at 37° C. was carried on for six days when the cultures were filtered through sterile Berkefeld V filters and the filtrate preserved with 0.4 per cent phenol. Sterility determinations in bouillon and tests on guinea pigs were carried out to determine the safety of the product.

The cutaneous reactions were done at the Wayne County Training School, the individuals tested ranging in age from eight to sixteen years with an average

of twelve years. Both sexes were represented, although males predominated. Only those reactions which were positive to strongly positive were accepted and reactions under 1 cm. in diameter were regarded as negative.

The results of skin tests with the toxins of 8 strains of streptococci isolated from hemorrhagic smallpox and 1 each of the comparative strains, may be seen in Table VII. The control toxin in each instance was heated at 100° C. for thirty minutes in the autoclave. Varying dilutions of the filtrates were made, and subcutaneous injections, given on the forearm of the individuals tested, were read in twenty-four hours. Dilutions were made so that 1 c.c. of the original filtrate would contain 3,000 skin test doses. The toxins from 01730, scarlet fever, 02168 erysipelas, and 02224 puerperal septicemia, had all been previously neutralized with convalescent serum and also by horse antitoxin produced by injection of organisms from scarlet fever (Dick), erysipelas (Birkhaug), and puerperal septicemia (Birkhaug).

A study of the table would seem to indicate some relationship between the smallpox strains and those of the streptococci from erysipelas and puerperal septicemia. Out of a total of 79 individuals tested, only 14 gave reactions to the erysipelas and puerperal septicemia toxins and no reaction to the smallpox toxins. Individuals reacting to the puerperal septicemia and erysipelas toxins and one or more strains of the smallpox toxins numbered 45. The results would also indicate that the smallpox strains are closely related in their ability to produce soluble toxins.

In order to prove conclusively that the substance causing the reactions in the intradermal tests was a true toxin, an effort was made to produce an antitoxin. The streptococcus immune serum or antitoxin would thus neutralize its own toxin when mixtures of toxin and antitoxin were injected intradermally into an individual who was susceptible to the toxin. The immune serums were produced by repeated intravenous injections of undiluted filtrate into rabbits. The first injection was 3 c.c. of filtrate followed every third day by increasing amounts until a maximum of 10 c.c. was given. The animals were bled ten days after the last injection. A control serum was obtained from nonimmunized (normal) rabbits. Equal amounts of diluted filtrate and a 1:20 dilution of both immune and nonimmune serums were mixed and allowed to incubate for one hour at 37° C. Varying dilutions of the antitoxin were used in the test. Persons who were positive to the toxin of one strain of the streptococci from smallpox were selected and injected as shown in Table VIII.

Individual variations in the persons injected account for several unwarranted reactions. Two of the group were sensitive to the serum while two others reacted to the protein. The antitoxin in a dilution of 1:10 neutralized the toxins from Var. 7 and Var. 8 although a 1:20 dilution showed no neutralization in 2 instances.

SUMMARY

From the results of this work it would seem apparent that certain differences exist between the hemolytic streptococci isolated from blood cultures of fatal hemorrhagic smallpox and the pyogenic type of organism of scarlet fever, erysipelas, and puerperal septicemia.

Morphologically, the strains of streptococci from smallpox are similar to those isolated from scarlet fever, puerperal septicemia, and erysipelas.

Classification of the streptococci by means of their action on certain carbohydrates would place the organisms from smallpox and those from scarlet fever, erysipelas, and puerperal septicemia, in two distinct groups, based on the inability of the latter to ferment lactose.

The controlling strains each produced an acid reaction in litmus milk while the strains from smallpox were all negative.

The virulence for mice of organisms from smallpox is low, the usual fatal dose, after repeated passage, being about 0.1 c.c.

Agglutination tests with both homologous and heterologous strains would indicate a different serologic grouping between the organisms isolated from smallpox and the comparative strains.

Complement fixation results run about parallel to the agglutination tests and are apparently no more specific.

Streptococci isolated from smallpox produce a specific toxin which when injected into susceptible individuals gives rise to a cutaneous reaction.

The antitoxin produced in rabbits is specific as it neutralizes the toxin while normal serum has no effect.

CHANGES IN BLOOD CONCENTRATION INCIDENT TO SHOCK*

V. H. MOON, M.D., AND PATRICK J. KENNEDY, M.D., PHILADELPHIA, PA.

MONOGRAPHS on clinical pathology and microscopy contain no references to blood changes in traumatic shock or in circulatory failure of similar character developing in other conditions. Occasional references to such changes are found in clinical reports, but their significance and diagnostic importance have not been emphasized.

In 1893 Sherrington and Copeman¹ observed that animals, subjected to prolonged experimental operative procedures, presently showed increased respiratory and pulse rate, and decreased temperature and blood pressure. This was accompanied by the development of edema and by increased concentration of the blood. They suggested the relationship of these phenomena to surgical shock. It is of interest that these observations forecast by twenty-five years the accepted interpretation of shock, and that the essential features of it including increased blood concentration were noted. Cannon, Fraser and Hooper,² observing the development of shock in wounded soldiers, found a red cell count of 6 million or more and a corresponding increase in hemoglobin as prominent characteristics. Robertson and Bock³ corroborated those observations. Keith⁴

Supported by funds from the Martin Research Foundation. Presented before the Physiological Society of Philadelphia, January 16, 1933.

showed that the increased blood concentration was due to loss of blood plasma and that it was accompanied by a marked decrease in total blood volume. These findings have been confirmed repeatedly. In shock produced experimentally an increased concentration of blood occurred so regularly that we used it as a criterion for shock in a study of the pathology of that condition.⁵

Dale, Laidlaw and Richards,⁶ by injections of histamine, reproduced experimentally in mammals all the physiologic manifestations of shock following trauma. They noted increase in the red cell count and hemoglobin as regular features. They found that histamine produces direct injury to capillaries, causing loss of tonus and increasing the permeability. Escape of plasma through damaged capillary walls resulted in concentration of the cellular elements of the blood. The visible circulatory changes produced by histamine are present in cases of traumatic shock and the mechanism of their production apparently is identical. In the final analysis the etiology of shock is loss of capillary tonus. Extensive capillary dilatation withdraws blood from currency as effectively as hemorrhage. The patient "is bled to death into his own capillaries."

Krogh⁷ of Denmark and Lewis⁸ of England have studied the physiology of the capillaries most extensively and intensively. Their results agree in showing that increased permeability and loss of tonus are produced by all types of damage to capillaries. Such damage may result from light, heat or cold, chemical agents both organic and inorganic, injurious bacterial products and particularly products of cellular injury, similar to histamine in action and in composition. Any of these agents appropriately applied, will produce the shock syndrome. One who, unaccustomed to light, exposes his skin surface to intense sunlight for a short time may develop shock in mild degree. Profound shock has resulted from overexposure to the sun. Similar results may follow overexposure to artificial light rich in ultraviolet rays. It is well known that shock regularly follows superficial burns, and that its degree is proportionate to the size of the burned area. The shock is profound and may be fatal if about one-third of the skin surface is burned or scalded. Many salts of heavy metals will produce shock if introduced into the circulating blood. Various organic compounds will produce similar disturbances. Sodium barbital, and closely related compounds used as sedatives, will produce shock when overdoses are taken. We have seen characteristic circulatory collapse develop in a dog following the intravenous injection of sodium barbital, 0.3 gm. per kg. of body weight. The blood pressure fell 94 mm. in three hours. The respirations and pulse rate became increased to twice the normal. The external parts became cold; there was 20 per cent increased concentration of the blood as shown by hemoglobin percentage and erythrocyte count. At postmortem examination all the changes which we have found to accompany shock were present. These, it should be emphasized, are identical to those observed by Dale, Laidlaw and Richards, following death from histamine (see Figs. 1 and 2). The abdominal and thoracic viscera had a deep rose-red color due to capillary congestion. The minute venules everywhere were engorged. The mucosae were dull red in color. There was blood-tinged fluid within the bowel tract and in the serous cavities.

The lungs were irregularly congested and their weight was increased. They contained innumerable small hemorrhages. Capillary hemorrhages were also present in the serous surfaces, the endocardium and in the lining of the gall-bladder and urinary bladder.

A man, aged thirty-four, took an unknown amount of "sedormide." Profound narcosis resulted and he was unconscious for eighteen hours. On admission to the hospital the red cells were 6,030,000 and the hemoglobin 118 per cent. On the following day the temperature was 97°, the pulse 130 and the blood pressure 110/70. There were moist râles throughout the chest and the percussion note was hyperresonant. Adrenalin, atropine, caffeine and pituitrin were given as stimulants. Fluids were given by mouth, by hypodermoclysis and by glucose solution intravenously. These were ineffective. Death occurred within seventy-two hours. The postmortem findings were characteristic of shock. There was general engorgement of all the body viscera. The venules and capillaries of the entire gastrointestinal tract were distended in both the peritoneal and mucosal surfaces. The lungs were extremely dark red, were almost airless and contained quantities of bloody fluid. Petechial hemorrhages were numerous throughout the lungs and in serous surfaces. Excepting the circulatory changes described, and the beginning of bronchopneumonia, microscopic examination showed no significant changes in any organs, including the central nervous system. It is stated⁹ that overdoses of sedatives belonging to this group of urea derivatives, cause a marked fall in temperature and of blood pressure due to paralysis of the peripheral vessels. Krogh's experiments¹⁰ with urethane showed that it affected the capillaries producing marked dilatation. He stated that other narcotics produce similar effects. Our microscopic examinations showed marked dilatation of the capillaries and venules in deaths from barbital and from "sedormide." Both the physiologic disturbances and the postmortem findings in such cases are indistinguishable from those of shock.

We have seen identical changes in dogs following the intravenous injection of killed bacterial cultures and following peritonitis experimentally produced. We were able to produce the typical shock syndrome in dogs by the intravenous or intraperitoneal injection of watery extract of normal dog muscle, by introducing muscle substance into the peritoneal cavity or by mechanical trauma to the limbs. In every instance the syndrome was accompanied by increased concentration of blood (Table I). In each instance the visible circulatory changes characteristic of shock were present. These findings support the conclusion that a wide variety of agents are capable of causing capillary damage, and that such damage results in circulatory failure with manifestations resembling traumatic shock.

Circulatory failure of this type, often spoken of as collapse, occurs in various clinical conditions. Toxemia with shock following intestinal obstruction is a common occurrence. It has been attributed to the absorption of histamine from the injured bowel. Underhill¹¹ noted circulatory collapse following gas poisoning and in influenzal attacks of extreme severity. In each of these instances increased concentration of blood was recorded. Atchley¹² noted the

shock syndrome in diabetic acidosis, in severe infections, and in one instance of a rattlesnake bite in which the venom apparently was injected directly into a vein.

TABLE I

CHANGES IN BLOOD CONCENTRATION IN A DOG. SHOCK WAS PRODUCED BY INTRODUCING SUBSTANCE OF DOG MUSCLE INTO THE PERITONEAL CAVITY. DEATH RESULTED IN 10.5 HOURS
BLOOD CONCENTRATION: SHOCK

TIME	SP. GRAY.	HEMOGLOBIN	RED CELLS
6:30 A.M.	1.060	101	5,110,000
7:00 A.M.	Muscle substance into peritoneum		
10:30 A.M.	1.065	104	4,860,000
1:30 P.M.	1.065	104	5,694,000
3:20 P.M.	1.067	108	5,695,000
4:50 P.M.	1.075	120	6,400,000
5:15 P.M.	1.075	130+	7,450,000

We have had opportunity to make examination following deaths from acute hemorrhagic pancreatitis, mesenteric thrombosis, intestinal obstructions, eclampsia, perforated intestinal ulcer, burns and other conditions in which the shock syndrome was a prominent antemortem feature. In each instance the blood changes and the postmortem findings were those seen in traumatic shock in man, and in experimental shock in dogs.

An experience as pathologist in a large charity hospital during the pandemic of influenza, 1917 to 1919, resulted in observations not interpreted at the time. Many of the most severe cases, which died in from two to four days from the onset, had increased concentration of blood. Red cell counts in such cases ranged from 6,000,000 to 8,000,000 and the hemoglobin was correspondingly high. The attending physicians came to regard this as a grave sign. Those patients with high concentration died early with evidences of circulatory collapse. There was a marked decline in blood pressure, weak pulse, rapid respirations and the temperature was lower than seen in cases less severe. Postmortem examination showed wet bloody lungs and extreme capillary congestion of the mucosae of the pulmonary and gastrointestinal tracts. The patients having moderate concentration of blood lived from seven to fifteen days. On postmortem examination the congestion and edema were not so extreme but were marked. Bronchopneumonia which was very irregular in its characteristics and distribution, was a regular feature. In the most severe cases no pneumonia was demonstrable either grossly or microscopically. The lungs had all the features seen in patients dying within two or three days from severe burns or from physical trauma. They presented no essential differences from the lungs following shock produced experimentally.

A young woman suffering from acute hemorrhagic pancreatitis was brought to the hospital. She had rapid weak pulse, rapid respirations, cold pale skin and falling blood pressure. No operation was done; the treatment was entirely symptomatic; she died of circulatory failure within forty-eight hours. Only one blood count was made. The red cells were 6,400,000 and the hemoglobin 112 per cent. At postmortem the visible changes characteristic of shock were present. The lungs were deeply congested, edematous, and heavy.

Their capillaries and venules were distended with blood, and there were numerous capillary hemorrhages within the lungs, in the pleurae and in other serous and mucous surfaces. The abdominal viscera were diffusely deep red and the minute venules were abnormally prominent. DeTakats and Mackenzie¹³ reported 9 cases of hemorrhagic pancreatitis, in all of which the red cells were about five million and the hemoglobin correspondingly high. One case had

Fig. 1.—Photograph of lung in shock, death within forty-eight hours following severe burn. Normal lung (left) for comparison.

Fig. 2.—Microphotograph of lung, shock following burns. Congestion, edema and capillary hemorrhage are shown.

8,300,000 red cells and 140 per cent hemoglobin. They recognized the shock syndrome in each of these cases and stated that blood counts furnished a means for estimating the degree of shock.

Underhill¹⁴ and his associates have emphasized increased concentration of blood as a clinical feature in burns. They failed to note the relationship of this to the mechanism of shock, but recognized it as a grave physiologic disturbance and applied suitable measures for its relief. The condition is well exemplified in the following cases:

Three men were seriously burned following a collision in which a gasoline tank was burst and ignited. The burns were of the second and third degrees involving chiefly the legs, arms, and faces. Shock was a marked feature in each case. The burns varied somewhat in the amount of skin involved and likewise the degree of shock varied. The man having the most extensive burn had a red cell count of 8,350,000 and the hemoglobin was 120+. The Dare hemoglobinometer which was used had no provision for higher readings. He died within forty-eight hours. The postmortem findings were typically those of shock⁶ (Figs. 1 and 2). Another, whose burns were slightly less extensive, died of secondary pneumonia eleven days later. His condition of moderate shock, as shown by blood pressure and concentration, continued during the eleven days. The circulatory changes at postmortem were the same as described. In addition there was diffuse bronchopneumonia in an early stage. This feature is especially significant. Lungs, whose circulation is impaired and whose spaces are filled with edematous fluid, present a stage already set

TABLE II

CHANGES IN BLOOD CONCENTRATION DURING RECOVERY FROM SEVERE BURNS. THE ACCIDENT OCCURRED DEC. 12, 1932; THE FIRST BLOOD EXAMINATION WAS MADE TWO DAYS LATER
BLOOD CONCENTRATION: BURN, RECOVERY

DATE	SP. GRAV.	HEMOGLOBIN	RED CELLS
12-14	1.075	120+	6,700,000
12-15	1.070	112	5,400,000
12-16	1.063	110	5,000,000
12-17	1.070	116	5,200,000
12-18	1.068	115	5,100,000
12-19	1.066	110	4,990,000
12-20	1.062	106	4,900,000

12-22	1.048	74	3,530,000
12-24	1.045	87	3,820,000

for the final act, the development of pneumonia. The third man who was burned recovered. The blood concentration, shown in Table II, declined gradually as the patient's condition improved.

SUMMARY

Increased concentration of the blood is a regular feature developing during surgical or traumatic shock.

Circulatory failure similar to shock is of frequent occurrence in conditions accompanied by toxemia. Such conditions include burns, toxemias of metabolic origin, poisoning with certain drugs, surgical emergencies such as intestinal obstruction, pancreatitis, and perforated ulcer, and infections of unusual severity.

Increased concentration of the blood, as shown by specific gravity, red cell count and hemoglobin content, is a feature in such cases. The degree of concentration apparently is proportionate to the severity of shock.

The circulatory changes seen at postmortem in such cases are indistinguishable from those of traumatic shock. These observations indicate that the mechanism of origin is essentially the same.

Observations on concentration of blood should be of value in detecting and estimating the degree of shock in clinical studies.

METAPLASTIC CHANGES IN THE PROSTATE GLAND*

LOUIS P. KASMAN, M.D., AND JOHN GOLD, M.D., BROOKLYN, N. Y.

HISTOLOGIC changes observed in 2 cases of prostatic hypertrophy were of such a character as to lead us to study the behavior of prostatic glandular epithelium.

The first case is that of a man fifty-nine years of age (No. 8,393) who was admitted to the hospital on May 17, 1931. His chief complaint was pain in the left loin and urinary retention of twenty-four hours' duration.

He had been suffering from polyuria, nocturia, and at times dysuria, and also complained of some difficulty in starting the urinary stream and periods of retention. This condition was present for more than five years. There was also loss of weight, digestive impairment, occasional night sweats and blood-streaked sputum.

Examination revealed an elderly undernourished male who appeared acutely ill. Bronchial breathing and a few moist râles were present at right apex and below the right clavicle. A presystolic murmur was heard. The abdomen was distended and presented an ovoid swelling which reached upward to the umbilicus. There was flatness on percussion over this area. Ten-

Received for publication, February 15, 1932.

derness was present in the left loin. No rigidity was present in the abdomen. The right Murphy sign was positive. Rectal examination revealed a large boggy mass present in the prostatic area with most of the enlargement to the left side. A small rigid catheter was introduced into the bladder with difficulty. Catheterization recovered 52 ounces of residual urine.

A cystoscopic examination showed a marked prostatic hypertrophy especially of the left lobe. There was a generalized cystitis.

White blood cells 16,500, polymorphonuclears 78 per cent, lymphocytes 18 per cent, monocytes 4 per cent, hemoglobin 93 per cent, red blood cells 4,000,000. Urine examination on admission was negative except for a trace of albumin. Blood chemistry showed urea nitrogen 38.5, creatinine 1.5, glucose 110, chloride 460.

On May 19 a suprapubic cystostomy was performed and a mushroom catheter placed in the bladder. The patient had a rather stormy postoperative course because of the myocardial weakness and finally developed pneumonia. He died on June 15.

No consent for a general autopsy was obtained, but we succeeded in removing the bladder and prostate through the surgical incision.

Macroscopically the prostate was considerably enlarged, particularly in its transverse diameter, while the anteroposterior diameter was but slightly increased. The gland was therefore of an elongated oval shape and appeared rather flat. Its size was about twice the normal and felt quite hard to the touch. The central portion showed a superficial irregular defect, the bottom of which was covered with some grayish yellow cheesy material. On cutting through this defect it was found that the grayish yellow discoloration extended irregularly to the depth and seemed to demarcate rather sharply in the form of a saw edged line, from the lateral apparently intact parts of the prostate.

Microscopic Examination.—There was an extensive necrotic area in the center with some leucocytic infiltration of the periphery and some small irregular hemorrhages. In the lateral portion the glands were of the type seen in ordinary prostatic hyperplasia. Their epithelium was high columnar and showed a clear faintly staining cytoplasm. Many glands, however, were lined with a very low cuboidal or flat epithelium and some glands were distended thereby forming cysts, quite a few of which were of considerable size. The amount of stroma was increased throughout, and it was of a fibrous hyaline character. Rather massive fibrous tissue was found in the vicinity of the necrotic focus. The glands which persisted in this scarry area were obviously atrophic, their lumen narrow and often collapsed. Some were transformed into solid epithelial trabeculae. The cytoplasm of these cells was scanty; the nuclei were comparatively large, well stained and round or spindle shaped. There were several solid islands of squamous epithelium between these atrophic glands, some of which showed central parakeratosis while others were almost completely keratinized with the exception of a peripheral seam of cuboidal cells forming a single layer (Fig. 1). In other groups of squamous cells hydropic vacuolization could be visualized. There were also a few small

cell groups in which only the central cells looked like squamous epithelium, whereas the periphery was formed by smaller cells of the basal cell type which showed striking palisading of their nuclei. Finally there were trabeculae consisting of squamous epithelium, scattered in the fibrous tissue and alternating with groups of smaller less differentiated cells. The general appearance of these foci resembled somewhat a scirrhous carcinoma.

Summarizing our findings, we found we were dealing with a glandular hyperplasia of the prostate with interstitial fibrosis and a central focus of anemic infarction, probably due to thrombosis. The fibrotic areas revealed regressive changes of the glandular epithelium, followed by proliferation and metaplastic transformation into squamous epithelium. Parakeratosis was quite conspicuous.

The second case was that of a man aged forty-four years (No. 8,063) who was admitted to the hospital April 20, 1930, complaining of difficulty in urina-

Fig. 1.—Island of squamous epithelium with parakeratosis (high power).

tion. The patient's illness dated back about two months when he first noticed nocturia and some hesitancy in starting the urinary stream. About four weeks later pain and burning occurred when he voided.

The physical examination was negative except for some tenderness suprapubically. There was a left lumbar scar of a previous nephrectomy. A positive right Murphy sign was present. Examination of the genitalia revealed a hypospadias. On rectal examination a large tender boggy prostate was palpable.

Urine examination showed a trace of albumin and some white blood cells. Blood chemistry showed urea nitrogen 50.3, creatinine 2.9, glucose 143 mg. per 100 c.c.

Cystoscopic examination revealed a marked chronic cystitis with a constriction of the membranous urethra. On pyelogram the right kidney was somewhat enlarged and ptosed. The right ureteral catheter entered the pelvis easily. The left kidney was not present.

On April 23, 1930, a suprapubic cystostomy was performed under spinal anesthesia and a Pezzar catheter sewed into the bladder. Postoperatively the patient's condition improved. This was shown by the decreasing nitrogen retention. On May 9 urea nitrogen was 31.7, creatinine 2.5.

On May 10 a prostatectomy was performed under spinal anesthesia. The patient's condition remained satisfactory until May 13 when he began to hiccup, his abdomen became distended and the temperature began to rise. In spite of the treatment instituted he did not respond well. At this time blood chemistry showed urea nitrogen 44.3, creatinine 5.0, glucose 186. He developed uremic coma with an accompanying hypostatic congestion of the lungs and died May 22, 1930.

The prostate removed was comparatively small, flat and adherent to the surrounding fat tissue. It was very hard and showed a fibrous structure on section with quite a few scattered irregularly formed narrow fissures which occupied mainly the central portion of the more superficial stratum.

Microscopically a fibrosed prostate was found with considerable lymphocytic infiltration, particularly about the very irregularly formed glands. These glands did not resemble the ordinary prostate glands. Some were tubular, others irregularly branching. They were lined with multiple layers of squamous epithelium often causing the lumen to become quite narrow and usually eccentric. Proliferation of the epithelium sometimes closed the lumen altogether and yielded solid epithelial structures. The epithelial cells were usually small, but with quite large nuclei which were round or oval and fairly intensely stained. In other places, particularly in the solid epithelial nests, the cells were smaller, the nuclei densely packed, darker stained, and rod or spindle shaped, thereby resembling basal epithelia.

Careful examination of many slides showed that particularly in the lateral portions a few glands could be found which revealed the ordinary prostatic epithelium with the folding and formation of papillae characteristic of hyperplastic prostatic glands. In some of these glands, transformation of the cuboidal or high columnar epithelium into much smaller cells with darker nuclei could be ascertained. These cells formed several layers and gradually transformed the ordinary appearance of the prostatic gland into such tubular structures as described above.

Summarizing these findings we concluded that we were dealing with a chronic fibrosis of the prostate, apparently of inflammatory nature with transformation of practically all the prostatic glands into tubular structures, lined with squamous epithelium or solid groups of squamous or basal epithelium.

Metaplastic changes of glandular epithelium concomitant with hyperplasia are known to occur in almost any glandular organ. This is the most logical explanation of the observation that glands or mucous membranes covered with columnar epithelium reveal foci of basal or squamous cells. This process was first described in the lungs by Goldzieher who showed that in chronic inflammatory conditions the columnar bronchial epithelium reverts first to cells of the basal type, the proliferation of these cells yielding occasionally considerable thickening of the mucosa and eventually occlusion of the bronchial lumen. The squamous cells form secondarily through differentiation

of the basal cells. This interpretation is based on the conception that the basal cell represents an indifferent type of epithelium to which the columnar cells may revert under unfavorable conditions. The basal cell is considered to be a multipotent cell, which is capable of differentiating into any other type of epithelium.

Goldzieher's explanation of bronchial metaplasia and hyperplasia of the

Fig. 2.—Squamous epithelium all along the wall of the prostate glands. In the center a solid island of squamous epithelium (low power).

Fig. 3.—Incipient basal cell proliferation substituting the columnar cells of the prostatic gland (high power).

basal cells has been accepted by all the later workers (Teutschlaender, Askanazy, Smith, Fried and others). The experimental studies of Wolbach and Howe have shown, furthermore, that changes similar to those seen in chronic infections can be produced in animals by a diet deficient in vitamins. Basal cell hyperplasia with concomitant metaplasia has been described since in other organs, such as, the pancreas and gallbladder (Krompecher, Roesiger).

The occurrence of solid epithelial nests and of squamous epithelium in the prostate is known since Aschoff demonstrated the physiologic growth of squamous epithelium during the late stage of fetal life. His work was corroborated by Schlachta, who is also of the opinion that remnants of this fetal squamous epithelium may persist in the adult. Schmidt was the first to observe extensive parakeratosis in such islands of squamous epithelium found

Fig. 4.—Advanced basal cell proliferation with beginning differentiation into squamous epithelium (high power).

Fig. 5.—Massive proliferation of basal cell, practically obliterating the glandular lumen (low power).

in the adult. He interpreted this lesion in accord with the conception of Schlachta, although these changes were found in close vicinity to an old prostatic abscess. Similar views were held by Tietze and Garfunkel, who observed squamous epithelium in the prostate of eunuchoid and also believed he was dealing with a malformation. Krompecher, however, in a detailed study on the prostatic glandular epithelium showed that there is no need for embryonal nests nor for the hypothetical malformations to explain the histo-

genesis of such squamous epithelium. Their origin from the ordinary glandular cells, or from the epithelium of the prostatic ducts can be clearly demonstrated. The process involved is identical with that which occurs in the bronchial mucosa. According to Krompecher the occurrence of such basal cell hyperplasia and secondary metaplastic differentiation into squamous epithelium is quite common and seems to evolve from regenerative processes in the course of chronic inflammation. In a large series examined for the presence of such epithelial changes, they were observed in 45 per cent of the cases. These figures coincide with our own observation. In reviewing 26 prostates removed during the last eighteen months, 11 cases (that is 41 per cent) show more or less marked hyperplasia with metaplastic changes. Other authors (Grassmann, Neller and Neuburger) give lower figures and estimate the frequency of what they term "atypical epithelial proliferation" at 25 per cent.

There is some difference of opinion as to the actual seat of the lesion. Wagenseil and Altmann believe that the squamous epithelium develops from the ducts of the prostate, whereas, Krompecher found the changes as a rule in the glandular epithelium proper. Our own observations bear out Krompecher's statements, as we frequently observed glands lined partly with ordinary epithelium, while other parts of the same gland already showed definite basal cell hyperplasia. The sections, described in this paper from which the photographs (Figs. 1 to 5) were made, were taken from the lateral portions of the gland so far away from the urethra that there could be no suspicion that the tissue described was urethral glandular tissue. The occurrence of parakeratosis in our first case is the third observation of this kind on record, including those of Schmidt and Altmann.

The changes described in this paper are not only morphologically interesting, but they are also of clinical importance. The presence of squamous epithelium, with or without keratinization and the formation of solid nests and plexi of basal cells in a place where such epithelium does not occur physiologically, may erroneously lead to the assumption of the presence of a neoplastic process. It has been stressed recently by Grassmann that these atypical epithelial formations closely resemble carcinoma, and it is often very difficult to make the differential diagnosis between such lesions and early cancer of the prostate. As a matter of fact there is a frequent coincidence between such changes and carcinoma. This has been noticed by Krompecher, who held the opinion that carcinoma of the prostate, if not of the adenomatous type, is preceded by and develops from such basal cell vegetations. This would explain the occurrence of both basal and squamous cell carcinoma of the prostate. Krompecher's interpretation is based not only on his direct observations in carcinoma of the prostate but also on the analogy with similar observations in other organs, particularly the lungs. A recent paper by Fried also emphasizes the importance of bronchial basal cell hyperplasia for the histogenesis of carcinoma of the lungs. This had already been suggested by Goldzieher.

SUMMARY

Two cases of extensive metaplasia of the prostatic glandular epithelium are described. The histogenesis of metaplasia is discussed in its relationship

to basal cell hyperplasia. The frequency of these changes in the prostate and their significance in the development of prostatic carcinoma is emphasized.

LABORATORY METHODS

THE DIAGNOSIS OF SURGICAL TUBERCULOSIS*

RELATIVE RELIABILITY OF LABORATORY METHODS

ROBERT McCULLEY HALBACH, Sc.M., M.D., TOMS RIVER, N. J.

AT THE New York Orthopaedic Dispensary and Hospital a considerable number of patients are seen with symptoms in a bone, joint, or associated soft tissue which indicate a probable tuberculous lesion. As the pioneer surgery of Dr. Russell A. Hibbs has thoroughly proved, the treatment *par excellence* in such cases is fusion of the affected joint. This presupposes that the diagnosis has been confirmed by methods that are subject to the least possible error.

The ideal method should demonstrate tuberculous infection whenever present and be equally reliable in its negative phase, but as yet no single test has reached this degree of perfection. However, by the judicious combination of several methods, each of considerable accuracy in itself, we believe errors in diagnosis can be reduced to a rarity, indeed, practically excluded.

In demonstration of this contention, we are reporting the results of laboratory examinations made upon all material received from April, 1930, to October, 1932, in which tuberculosis was the object of search. Results are divided into Period A (from April, 1930, to September, 1931, inclusive) and Period B (from October, 1931, to October, 1932, inclusive) since the technic was changed in the latter group. All specimens were examined or confirmed by the author.

TABLE I
PERIOD A—TISSUES (TOTAL 103)

Histology positive—Guinea pig positive	52
Histology positive—Guinea pig negative	7
Histology doubtful—Guinea pig positive	1
Histology doubtful—Guinea pig negative	0

That is, inoculation confirmed 89 diagnoses, changed 2 to positive and failed to confirm or supplement 12, a percentage reliability of 88.4. Of the

*From the Department of Pathology; New York Orthopaedic Dispensary and Hospital. Received for publication, March 1, 1933.

7 animals which were negative while the corresponding tissue was positive by section, it is most probable that the tissue for inoculation was insufficiently macerated or injected in inadequate amounts, since in three cases subsequent tissue from the same lesion area yielded positive animals. In the tissue which was negative histologically but from which a positive pig was obtained, the material for section came from the head of the femur and that for inoculation from the ilium.

TABLE II
PERIOD A—JOINT FLUID OR PUS (TOTAL 69)

Guinea pig positive	45
Guinea pig negative	19
Guinea pig not supplementary—intercurrent death	5

Percentage reliability in this group was 92.8. Of these 69 specimens, positive animals were obtained in all that revealed acid-fast bacilli by staining. There were 41 which also had tissue sectioned from the same lesion area and the diagnoses agreed in 35, 3 were positive while the fluid or pus was negative, and 3 could not be checked because the pig with corresponding pus died of intercurrent disease.

In summary for Period A, a total of 172 specimens were examined. In 153, animal inoculation confirmed other methods, in 2 it changed a diagnosis to positive, and in 17 it failed to supplement, a percentage reliability for this period of 88.9. Moreover, in at least 3 cases examination of tissue from exploration revealed tuberculosis when the aspirated fluid or pus had been negative.

The factors of intercurrent deaths of some pigs and failure of others to confirm definite histologic evidence of tuberculosis in the above series constituted a serious defect, and in October, 1931, we adopted the technic given at the close of this report, and with the following results:

TABLE III
PERIOD B—TISSUES (TOTAL 57)

Histology positive—Guinea pig positive	33
Histology positive—Guinea pig negative	0
Histology negative—Guinea pig negative	20
Histology doubtful—Guinea pig positive	2
Histology doubtful—Guinea pig negative	1
Histology supplemented—pig died of pyogenic infection	1

That is, inoculation confirmed 54 diagnoses and settled 3 otherwise doubtful diagnoses. Percentage reliability of inoculation in this group was 100. In each of the 2 tissues doubtful by section both animals died of tuberculosis and in the one tissue doubtful by section both animals were negative. In the tissue classed as supplemented, both animals died (four and six days after inoculation) of a staphylococcus peritonitis, the tissue by section was a definite pyogenic inflammation and culture of tissue yielded staphylococci. In 4 other specimens one animal died of intercurrent disease but its duplicate subsequently died of tuberculosis or was negative by autopsy after sixty days.

TABLE IV
PERIOD B—JOINT FLUID OR PUS (TOTAL 28)

Guinea pig positive	18
Guinea pig negative	10
Guinea pig nonconclusive	0

Percentage reliability of inoculation in this group was 100. All material in which acid-fast bacilli were found yielded positive pigs. In 17 cases tissue from the same lesion area was examined and the diagnosis agreed with the findings from fluid. Also in this group 4 animals died of intercurrent disease but the duplicate remained to complete the diagnosis.

During the interval covered by both periods there were also 8 spinal fluids inoculated into animals with no intercurrent deaths; and 18 urine sediments inoculated with one death from intercurrent disease in period A. This last animal, however, did not develop pneumonia until the fifty-fourth day after inoculation and at autopsy its spleen, liver and lymph nodes were negative, so that it may properly be considered as negative for tuberculosis.

From the results in Period B we therefore feel that tuberculosis of the bones, joints and associated soft tissues can be diagnosed or excluded with great reliability if the following methods of examining material are employed:

Tissue.—In the absence of conclusive evidence from pus, fluid, etc., and with the physical findings indicative of tuberculosis, exploration is performed and several small portions of suspected tissue removed. A frozen section of a portion is made at once and, if diagnosed positive by an experienced observer, any therapeutic surgery that may be indicated can be proceeded with. In such cases completion of tissue section by paraffin or celloidin is the only confirmation needed. Without frozen section or when it is not clearly positive, a portion of tissue is expeditiously sectioned by celloidin or paraffin and, pending its completion, a similar portion prepared as follows:

Place tissue in sterile glass mortar, add from 5 to 8 c.c. of sterile saline and a small amount of sterile emery (medium) powder, and macerate thoroughly; add an equal amount of 6 per cent sulphuric acid, mix and place in 37° incubator for thirty minutes; transfer all but coarse fibers and emery sediment to centrifuge tube with a pipette and run at high speed (from 2,500 to 3,000 r.p.m.) for thirty minutes; remove supernatant fluid, resuspend sediment in 6 c.c. of sterile saline and set aside in ice box.

Sections should be completed within three to four days and, if cytology is clearly tuberculous, no further confirmation is needed and prepared sediment in ice box is discarded. When sections are negative or doubtful, proceed with animal inoculation of prepared sediment as follows:

Use guinea pigs of from 250 to 300 gm. that have been quarantined for three weeks following receipt in laboratory. For each sediment suspension inoculate two pigs both intraperitoneally, giving one 2 cc. and the other 4 c.c. Each animal is housed in a separate cage and observed daily. Inoculated pig is killed when appreciably ill or at the end of sixty days. When autopsied by an experienced observer, typical gross tuberculous lesions of spleen, liver, etc., are considered conclusive; otherwise, or when gross lesions are doubtful, acid-fast stains on smears made from involved viscera shall be the final criterion.

Pus.—Routine cultures and smears for Gram's and acid-fast staining are made. The remainder, up to 5 c.c., is treated with an equal amount of 6 per cent sulphuric acid, etc., as under preparation of tissue sediment, and the resuspended sediment inoculated into two animals in like amounts.

Joint Fluid.—Immediately on withdrawal mix with several cubic centimeters of sterile sodium citrate ($2\frac{1}{2}$ per cent) solution to prevent coagulation and then proceed as with pus.

Spinal Fluid.—Unless distinctly turbid or pyogenic organisms found in smears, inoculate directly into two animals, using 3 c.c. and 6 c.c. respectively. If turbid, or pyogenic organisms are present, treat a 10 c.c. portion with sulphuric acid, etc., as under pus, resuspend sediment in 6 c.c. of saline and inoculate in amounts of 2 c.c. and 4 c.c.

SUMMARY

Laboratory methods for the diagnosis of surgical tuberculosis and results of their use are given which, the author believes, warrant the following conclusions:

1. By these methods tuberculosis can, with rare exceptions, be definitely diagnosed or excluded.

2. Negative results by any or all of these methods in the case of joint fluids or pus do not completely exclude tuberculosis. In such cases, where the physical findings, etc., remain suspicious, exploration and examination of tissue are indicated.

IMPROVED DRINKING FOUNTAIN FOR SMALL LABORATORY ANIMALS*

DOUGLAS P. MURPHY, M.D., PHILADELPHIA, PA.

IT IS convenient to attach the water reservoirs to the outside of the doors when cages are stacked closely, and one upon the other. The inverted bottle type of drinking fountain is inexpensive and lends itself readily to this purpose.

Large bottles require simple curved or angulated glass nipples. Bottles of not more than 100 c.c. capacity are required for cages with doors only 8 inches high, in order that they will not prevent the opening of the door of the cage immediately above. The partial vacuum created by the inversion of the small bottle using simple curved or angulated nipples may impede greatly, or prevent entirely, the flow of water. The nipple shown in Fig. 1 was devised and has proved satisfactory in overcoming this difficulty.

It is made of glass tubing 9 mm. in outside diameter, and is blown in the form of a gentle curve instead of with an angulation. The lower part is

*From the Gynecean Hospital Institute of Gynecologic Research, School of Medicine, University of Pennsylvania.

Received for publication, February 2, 1933.

tapered to approximately one-half of its original diameter, and the open end is pressed into the shape of an hourglass.

The hole at the middle of the nipple is its most important feature. As the animal drinks by licking the end of the nipple, bubbles of air form at the hole in the midpoint of the nipple, enter, glide easily around the curve and rise to the surface of the water where they tend to equalize the partial vacuum. As a result, the animal has no difficulty in drinking.

The curve of the nipple facilitates the uninterrupted movement of the bubbles of air.

Fig. 1.—Showing construction and mode of operation of glass nipple suitable for 100 c.c. inverted bottle type of drinking fountain, attached to the outside of cage door. Note especially the 1 mm. diameter hole in the nipple at the midpoint of the curve and upon its concave aspect; also that the bubbles of air form at this point as the animal drinks.

The position and size of the hole, however, are the most important considerations in the construction of the nipple. The best site for the hole is on the concave aspect of the curve at its midpoint. Its optimum diameter is 1 mm. If the hole is smaller, the bubbles form with great difficulty if at all. If the hole is larger than 1 mm., they form more readily, are larger and more numerous, but when the animal stops drinking, they continue to form and the bottle empties automatically.

The credit for developing the nipple belongs to Charles W. Miller, glass blower, The Laboratories, Philadelphia General Hospital.

A SIMPLE AND EFFICIENT REFLUX CONDENSER*

A. BERNHARD, NEW YORK, N. Y.

IN THE determination of cholesterol in blood serum and plasma, reported in a previous communication,¹ it was found that the test tube condenser utilized was subject to certain mechanical difficulties. The water passing through the condenser had to be carefully regulated so that the pressure would not be too great; also, a slow boiling water-bath was essential to prevent condensation of steam into the Folin tube with subsequent interference with the color formation.

Fig. 1.

All defects were obviated by the use of the condenser shown in Fig. 1. The entire condenser is a single unit of glass, the top of which is made mushroom shape.

The condenser can be used with a vigorously boiling steam bath, and with a greater rate of flow of the condenser water, thereby increasing the efficiency of the condenser.

The particular shape of the condenser and the manner in which it fits the top of the Folin tube prevent any condensation of steam on the inside of the Folin tube.

The condenser was made by Eimer and Amend, New York, N. Y.

CYTOLOGIC STUDY OF BODY FLUIDS*

A. A. EISENBERG, M.D., HARRY WALLERSTEIN, M.D., AND AARON PLATO, B.Sc.,
NEW YORK, N. Y.

AN INFREQUENTLY practiced but highly valuable aid to diagnosis has reappeared in the literature following a lapse of several years. It is not at all uncommon for the medical practitioner to encounter a patient with a seemingly unaccountable effusion in one of the body cavities. That mechanical and metabolic factors, nonneoplastic in nature, may be the cause of such an effusion is a well-established fact. It is also known that certain inflammations, bacterial, chemical, or otherwise, may produce this fluid. It becomes the problem of the practitioner, in such an instance, to determine whether the effusion is due to one of the above factors, or whether it is produced through the mechanism of a neoplasm of the serous membrane or its circulatory supply. Roentgenologic study in these cases is usually of little value unless the fluid is removed before radiography. Even then, the uncertain data gathered from the x-ray (as to the nature of the dyscrasia, whether inflammatory or neoplastic, and if neoplastic, whether primary or secondary) can be transformed into certain knowledge by a study of the cells found in that fluid. For these occasions, it has become possible, in recent years, to offer a valuable and quite accurate aid to the diagnosis, in the rôle of a cytologic study of the fluid sediment.

Since the publication of Mandlebaum's technic for cytodagnosis of serous fluids appeared in 1917, it has been possible, with a considerable degree of accuracy, to rule out cardiac, inflammatory and metabolic disturbances, to determine whether a given serous effusion has a neoplasm as its source.

Mandlebaum's achievement followed upon the investigations of many workers who slowly, and step by step, prepared the field for the modern-day methods of single tissue cell diagnosis. Attempts to identify tumor cells in body fluids date back to 1860 when Beale² first noticed large multinucleated cells in unstained smears of sputum in a case of carcinoma of the pharynx. Little attention was paid to this, as well as to the work of Quinke³ and of Ehrlich,³ each of whom in 1882 demonstrated with new staining methods the presence of tumor cells in smears of pleural and peritoneal effusions. The first attempts at using cut sections were made in 1895 by Bahrenberg¹ who allowed a large quantity of fluid to clot spontaneously and then hardened the clot in alcohol, imbedded it in celloidin and cut it as a tissue. In 1900, Mandlebaum⁴ demonstrated the presence of actinomyces in pus, by means of tissue-like sections, and it is this method which he described in 1917⁵ as being of value when seeking tumor cells in fluids, and which has become the foundation upon which all later methods were based.

*From the Pathological Laboratories, Sydenham Hospital.
Received for publication, April 19, 1932.

Mandlebaum's method, as practiced at Mount Sinai Hospital in New York was the basis for a very exhaustive report in 1928 by Zemansky,⁷ who evaluated 914 examinations made at that institution over a period of fifteen years. His conclusions show that this study can be of inestimable value in arriving at a diagnosis. He emphasized also the worth of a positive report, stating that a negative report was not as conclusive, since the cells could be destroyed or missed even when present. His positive results, however, he regarded as being almost pathognomonic, since in the presence of a sheet of epithelial cells or of only a single cell with mitotic figures, an accepted diagnosis of neoplasm could be made. His checked results bore out these conclusions. At this point it may be advisable from our experience to add a cautioning statement: occasionally a sheet of endothelial cells may be present, having desquamated from the serous membrane. This may closely resemble squamous epithelium or even the medullary cells in a solid carcinoma (Fig. 1).

Fig 1.—Note sheet of large, pale, peritoneal cells. These are not neoplastic.

In his large series of cases Zemansky was able to arrive at an accuracy of 90 per cent in his positive results as compared to an accuracy of only 47 per cent in his negative results.

In the much shorter series that we have to report, we have been more fortunate in gaining a somewhat higher percentage of correct results. Over a period of five years, we have had 26 patients on whom we have made 39 examinations. Of these there were 32 positive diagnoses, with one case disproved (Case 25), for an accuracy percentage of 96.9 per cent. In only 7 cases were negative diagnoses made, and these were all checked as nonneoplastic, for an accuracy percentage of 100 per cent. From these statistics it can be seen that in all our cases where tumor cells could have been expected to be present they were found at the microscope. In no positive case was the diagnosis missed, as all our negative results were checked as such by the subsequent history of the case.

Though our series is too short to make the accuracy percentages definitely acceptable, we feel that our results have been so good as to justify the describing of our method, which is a modification of Mandlebaum's, and which we be-

lieve more readily preserves the cells, thus increasing the number of positive diagnoses, decreasing the number of negative diagnoses, and giving a greater general accuracy in cytologic study by this method.

Technic.—The original technic as described by Mandlebaum consisted in preparing the fluid sediment for cutting as a tissue section. This he did by centrifuging the fluid in large conical tubes and getting a sediment which he hardened in 10 per cent formalin and then ran through the alcohols, through chloroform and into paraffin. The hardened block of sediment was then cut, stained and mounted as a tissue section.

The accuracy of the positive results is well attested to by Zemansky's experiences, but the negative results are painfully inaccurate. The reason for this is obvious. In any test where the result depends on the finding of a few isolated cells, a number of factors may enter to cloud the picture. It is possible, for instance, to have a neoplasm involving the pleura with a consequent effusion, and yet have no tumor cells in that fluid. It is possible that no cells have desquamated. It is also possible that so few cells have desquamated that they are extremely difficult to find. For that reason Mandlebaum cautioned that as much fluid as is possible should be obtained and centrifuged. Another possibility is that the tumor cells, subjected to a prolonged sojourn in an environment to which they are certainly not adapted, may be changed to a considerable extent, and that the strenuous regime of fixation, dehydration, clearing, and infiltration to which they are subjected, may so further distort them as to make them unrecognizable, or that these processes may destroy the cells completely. It is true that most frequently the cells remain recognizable in sufficient numbers to permit a correct diagnosis. But, as Zemansky stated, it often happens that one gains an impression that there is a malignancy present, while still unable to give a diagnosis, and also one occasionally gives a negative diagnosis, only to find on subsequent examination or in the future course of the case that a neoplasm was present.

It is for these reasons that we have slightly modified Mandlebaum's technic, seeking to produce less strain on the chemical and physical properties of the neoplastic cells, and thus more often preserving them for diagnosis. The method employed is as follows:

1. Obtain sediment by centrifuging the fluid in large conical tubes at from 1,200 to 1,700 revolutions per minute for from one-half to one hour. Wash sediment several times in normal saline solution.
2. Decant supernatant fluid. Replace with about 25 times the volume of 5 per cent formal acetic acid, at 37° C. for from four to six hours.
3. Dehydrate by steeping through the following solutions:
 - a. 75 per cent alcohol for one hour
 - b. 95 per cent alcohol for one hour
 - c. 2 parts absolute alcohol and 3 parts ether for one-half hour
 - d. ether for one-half hour
 - e. 2 parts ether and 3 parts acetone for one-half hour
 - f. acetone for one-half hour

4. Clear in choloroform.
5. Infiltrate with paraffin at 45° C. gradually increasing the temperature so that in two hours it reaches 56° C.
6. Embed in paraffin as with ordinary tissue blocks.
7. Cut with sharp knife at slight angle, thus exposing a greater surface of the sediment for staining.
8. Staining and mounting is carried out as for routine tissue work.
9. Cut many slides to decrease chance of missing cells.

Comment.—1. Five per cent formol acetic acid is used as a fixative in place of 10 per cent formalin because the latter fixes the cells too rapidly and may produce considerable distortion, while the former permeates through the cells more slowly without injuring their structure.

2. The sediment is dehydrated more slowly and in a graded manner, again avoiding rapid, distorting changes in their appearance.

3. Cutting the block with the knife edge at a slight angle exposes a greater surface of cells and nuclei for staining.

CASE REPORTS

CASE 1.—Mrs. R. D., a white female aged forty-eight years, was admitted to Sydenham Hospital on Oct. 7, 1932, with symptoms of an enlarging abdomen for some weeks and

Fig. 2.—Authors' Case 1. Abdominal fluid. Diffuse peritoneal carcinomatosis. A. Note acinus formation.

with urinary disturbances. A roentgenologic series was of no aid. There were 8,000 c.c. of straw-colored fluid in the abdomen, which on examination by the above method showed adenocarcinoma (Fig. 2). Laparotomy revealed large thick, white patches on the parietal peritoneum and between the uterus and urinary bladder. The cecum was immovable. Microscopically these patches showed diffuse carcinomatosis.

CASE 2.—Mrs. J. G., a white female aged sixty-nine years, was admitted to the Sydenham Hospital on Aug. 23, 1932, with a pleural effusion on the right side. A chest tap was productive of 1,600 c.c. of light amber fluid, which showed many small clumps of dark staining epithelial cells. A diagnosis of metastatic carcinoma was made, and again at two subsequent tappings, at which occasions bloody fluid was removed. During this time it was learned that four years previously the patient had had a left-sided mastectomy for carcinoma.

CASE 3.—Mrs. V. M., a white female aged twenty-nine years, was admitted to the Sydenham Hospital on June 2, 1932, with the diagnosis of serous pleurisy, possibly tuberculous. Examination of the fluid showed the absence of tumor cells, and the presence of an exudate with a large preponderance of lymphocytes and some hyaline material resembling

caseation. No giant cells were seen. A diagnosis of probable tuberculosis was made, and confirmed by the result of guinea pig inoculation.

CASE 4.—Mrs. B. B., a white female aged forty-three years, was admitted to the Sydenham Hospital on Nov. 16, 1931, with fluid in the right chest, cough and pain on that side. A tap was productive of 750 c.c. of sanguinous fluid which showed on cytologic study large groups of neoplastic cells of the kind frequently seen in tumors of the ovary. Six subse-

Fig. 3.—Authors' Case 4. Chest fluid. A, Note mitoses; B, double nuclei.

Fig. 4.—Same case as Fig. 3. Chest fluid. Note close resemblance to cells in ovarian carcinoma.

quent thoracenteses resulted in the same findings and gynecologic examination disclosed a large mass in the left adnexal region. Operation was performed and both ovaries removed. Microscopically there was a bilateral papillary adenocarcinoma of the ovaries Figs. 3, 4, and 5.

CASE 5.—Mrs. R. N., a white female aged thirty-four years, was admitted to the Sydenham Hospital on Feb. 3, 1932, with a cough and a left-sided pleural effusion. Aspiration resulted in a sanguinous fluid that showed a denocarcinoma on microscopic study (Fig. 6). The roentgenologic diagnosis after the tap was metastatic involvement of the lungs secondary to pleural malignancy.

CASE 6.—Mrs. B. F., a white female aged fifty-six years, was admitted to the Sydenham Hospital on Feb. 15, 1932, with pain in the chest, dyspnea even at rest, and paroxysms of coughing. There was no hemoptysis, and no signs of congestive circulatory failure.

Thoracentesis was productive of a hemorrhagic fluid which showed a probable pleural endothelioma. This was confirmed by x-ray, and later by necropsy at another institution (Fig. 7).

CASE 7.—Mrs. H. B., a white female aged eighty-three years, was admitted to the Sydenham Hospital on Dec. 21, 1931, with a cystic mass the size of an orange in the right kidney region. It was found to be a cyst in the sacroiliac joint. The aspirated fluid showed an epithelial malignancy. Other metastatic foci were found at radiographic study, but the primary tumor was not located.

Fig. 5.—Papillary adenocarcinoma (bilateral). Same case as Fig. 3. Ovarian tumor. A, Note resemblance to cells in chest fluid.

Fig. 6.—Chest fluid in case of breast carcinoma. A, Note ductal formation and resemblance to breast tumors.

CASE 8.—Mrs. P. K., a white female aged thirty-eight years, was admitted to the Sydenham Hospital on March 20, 1930, for parturition, with cough and pain in upper right chest. Two years previously she had had a right mastectomy for carcinoma. Roentgenologic study showed fluid in the right pleural cavity. At thoracentesis a hemorrhagic fluid was found, which on section of the sediment with microscopic study thereof showed sheets of neoplastic epithelial cells. The patient later died at another institution.

CASE 9.—Mr. M. L., a white male aged forty-two years, was admitted to the Sydenham Hospital on April 25, 1932, with generalized icterus, loss of weight, weakness, and a vesicular

rash on his lower extremities. The axillary and inguinal lymph nodes were considerably enlarged. There was a marked pleural effusion which was tapped on two occasions, and each time showed the presence of many eosinophiles, reticulum cells, endothelial cells, and a suggestion of Dorothy-Reed cells. The diagnosis of Hodgkin's disease was made, and confirmed by the subsequent course of the disease, although no biopsy was made. The patient is under a deep x-ray therapy and follows a typical Hodgkin's disease course.

CASE 10.—Mr. J. S., a white male aged forty-three years, was admitted to the Sydenham Hospital with a history of sudden ascites that came on a few weeks previously. At

Fig. 7.—Authors' Case 6. Chest fluid. Note typical foamy cells with vesicular nuclei. A, Mitoses; B, double nuclei.

Fig. 8.—Authors' Case 8. Abdominal fluid. Note diffuse carcinomatosis. Scirrhous type arrangement.

laparotomy there were 10 quarts of fluid and a diffuse peritoneal carcinomatosis. Examination of the fluid sediment showed numerous large spheroidal epithelial cells with acidophilic cytoplasm and pyknotic nuclei (Fig. 8). The primary focus was not located.

CASE 11.—Miss M. H., a white female aged thirty years, was admitted to the Sydenham Hospital on May 3, 1929, with vague abdominal pains and ascites, associated with loss of weight and strength. The abdominal fluid was aspirated and showed numerous epithelial cells of various sizes and shapes with numerous mitotic figures. There were many large

cells, hydropic with the nuclei displaced to the periphery giving the typical "signet ring" cells (Fig. 9). The diagnosis was confirmed at operation.

CASE 12.—Mrs. B. H., a white female aged sixty years, was admitted to the Sydenham Hospital on July 3, 1929, with a history of diabetes, complaining of dyspnea, and having fluid in the chest. Thoracentesis resulted in a hemorrhagic fluid which showed microscopically many epithelial cells piled up on a fibrinous basement membrane in papillary arrangement. A diagnosis of papillary carcinoma was made, but was not substantiated since the patient left after the fluid recurred, and has not been heard from.

CASE 13.—Dr. S. H., a white female aged forty-seven years, was admitted to the Sydenham Hospital on Nov. 6, 1930, with dyspnea, cough, abdominal distention, and vague pains in the abdomen and chest. Radiograph disclosed the presence of large abdominal glands, and fluid in the chest. Hemorrhagic fluid was removed which showed many pus cells and numerous reticulum cells and eosinophiles with endothelial cells of the type seen in Hodgkin's disease. The diagnosis was confirmed by biopsy.

CASE 14.—Mr. J. S., a white male aged thirty-six years, was admitted to the Sydenham Hospital on Jan. 27, 1932, with cough, expectoration of tenacious sputum (often blood-tinged)

Fig. 9.—Authors' Case 11. Abdominal fluid. A. Note typical "signet ring" cells as seen in Krukenberg tumor of ovary.

and dyspnea with pleuritic pain on both sides of the chest. At thoracentesis a hemorrhagic fluid was aspirated which showed many sheets of epithelial cells, many with mitotic figures. A diagnosis of epithelial malignancy was made, and in March, two months later, bone metastases were found. The patient died shortly afterward, and since no autopsy was performed the primary focus was never ascertained.

CASE 15.—Mrs. C. C., a white female aged thirty-seven years, was admitted to the Sydenham Hospital on April 7, 1932, with a postpneumonic lung abscess, and fluid in the right chest. Aspiration was productive of a thick yellow fluid which showed no tumor cells, and many leucocytes. A negative diagnosis was made, and the patient subsequently recovered.

CASE 16.—Mrs. B. H., a white female aged fifty-eight years, was admitted to the Sydenham Hospital on Dec. 5, 1932, with precordial distress, weakness and loss of weight (50 pounds in two years). Her sputum was mucoid and blood-streaked. Large nodes were felt in the region of the bifurcation of the carotid (right). Aspiration of the fluid in the right pleural cavity produced brownish yellow fluid which showed on microscopic examination numerous spheroidal epithelial cells with round vesicular nuclei and many mitotic figures. A diagnosis of epithelial malignancy was made, and confirmed by x-ray, but the primary focus was never found.

CASE 17.—Dr. A. W., a white male aged fifty-two years with loss of weight and painless jaundice for six months. He had had a cholecystectomy two years previously, and prior to that had had a finger amputated because of an epithelioma which had developed due to his work with x-rays. The growth never recurred. Shortly before his death he developed an ascites, which was aspirated and showed a clear amber fluid with many spheroidal epithelial cells with irregular nuclei and mitotic figures. A clinical diagnosis of carcinoma of the pancreas was made, but no further substantiating evidence was forthcoming.

CASE 18.—Mrs. T. S., a white female aged eighty-five years, with urinary disturbances, frequency, dysuria. Her bladder was washed and the washings on two separate occasions examined as for cells in an effusion. The microscopic study showed many inflammatory cells and many sheets of papillomatous formations, that showed malignant changes in the cells. A diagnosis of papilloma with malignant degeneration was made and confirmed by the cystoscopic examination.

CASE 19.—Mr. A. L., a white male aged fifty-three years, was admitted to the Sydenham Hospital on April 4, 1931, with complaint of pain in the right chest. Several tapplings were productive of straw-colored fluid which failed to show any neoplastic cells, but did contain many lymphocytes and monocytes. Radiography disclosed a large mass in the middle lobe of the right lung, and a diagnosis of pulmonary neoplasm was made notwithstanding the negative reports from the laboratory and the presence of a positive Wassermann test. At autopsy a large gumma of the lung was found.

CASE 20.—Mr. S., a white middle-aged man was found by his physician to have fluid in the pleural cavity. The physician aspirated this fluid, which was hemorrhagic in nature, and brought it to the laboratory for cytologic study. Paraffin sections of the sediment showed many plasma cells and many large, foamy cells, probably endothelial in origin with double nuclei and mitotic figures. A diagnosis of probable pleural endothelioma was made, but was not confirmed as the patient was lost track of.

CASE 21.—Baby T., a white male aged three and one-half years, was brought to his physician in a state of suffocation. The doctor suspected an enlarged thymus, had the child studied radiographically, and found fluid in the pleural cavities with diffuse nodular growths in the lungs. Study of the fluid sediment showed many lymphocytes and monocytes with many reticulum cells. A diagnosis of mediastinal lymphosarcoma was made and confirmed by the x-rays and subsequent course of the disease. The child was improving remarkably with deep therapy, but finally succumbed after two years.

CASE 22.—Mrs. W., a white female aged sixty years, was treated by her physician for fluid in the chest. She had rapid refilling after each tapping. The fluid was hemorrhagic in nature and microscopically showed many sheets of palisade-arranged cells which were uniformly round and oval, foamy with vesicular nuclei. A diagnosis of pleural endothelioma was made and confirmed by autopsy later.

CASE 23.—Mrs. E. W., a white female aged fifty-eight years, was admitted to the Sydenham Hospital on Jan. 10, 1933, with abdominal ascites. She had been laparotomized at another hospital several months previously, and was admitted to this institution for paracentesis. A paracentesis resulted in 1,800 c.c. of straw-colored fluid which showed numerous epithelial cells in solid clumps and in acinous formation. Many mitotic figures were seen. A diagnosis of epithelial malignancy was made and confirmed by the previous laparotomy.

CASE 24.—Mrs. A. M., a white female aged sixty-two years, was admitted to the Sydenham Hospital on Sept. 26, 1932, with marked anemia, some jaundice and a history of loss of twenty-five pounds over a period of three months. A calculus was found in the left kidney and also a lumbar arthritis was discovered. There was an abdominal ascites which at paracentesis yielded a straw-colored fluid. Microscopic study failed to reveal any neoplastic cells. At operation there was a chronic cholecystitis with stones in the cystic and common ducts. She proceeded to make an uneventful recovery.

CASE 25.—Mrs. D. G., a white female aged thirty-seven years, was admitted to the Sydenham Hospital on June 9, 1931, for hysterectomy for a fibroid uterus. She had an uneventful recovery and was discharged, but returned on Dec. 8, 1932, with ascites and a rup-

tured duodenal ulcer. The abdominal fluid was examined microscopically and a diagnosis of an epithelial malignancy was made, but not confirmed at operation.

CASE 26.—Mrs. M. D., a white female aged forty-one years, was admitted to the Sydenham Hospital on Jan. 27, 1933, with a history of illness for four months, her symptoms simulating an acute upper respiratory infection. Her condition became progressively worse and the loss of weight became marked. She developed a large amount of fluid in the right pleural cavity. A thoracentesis was productive of 600 c.c. of bloody fluid, and three days later 400 c.c. more were removed. Microscopic study of the sediment showed an epithelial neoplasm. The radiographs gave a picture of primary growth of the lower lobe of the right lung.

SUMMARY

1. There is presented a modification of the present-day methods of utilizing the sediment in exudates as tissues for histologic study. This modification causes less stress on the chemical and physical properties of the cells, thus preventing their distortion and preserving them for diagnosis.

2. Twenty-five cases, carefully checked up by subsequent histories, operations, and autopsies whenever possible are added to the literature.

3. The authors feel that the study of fluid sediments from a histopathologic viewpoint can prove a very valuable adjunct to clinical diagnosis, in addition to pointing the way for therapy in doubtful cases.

SIMPLE METHOD OF DRYING PIPETTES*

VIRGINIA M. WALKER, MOBERLY, MO.

A SIMPLE and inexpensive device for drying pipettes, where a laboratory does not have access to compressed air, may be made by using an ordinary air pump for automobile tires.

This pump may be fastened securely in an upright position on the worktable near the sink. The rubber tubing is placed over the end of the pipette, and two or three pressures of air will be sufficient to dry any pipette of ordinary size.

If one has a properly fitting adapter for a Luer type syringe, it may be placed on the end of the rubber tubing and hypodermic needles dried in the same way.

THE PURIFICATION OF GUM DAMMAR FOR USE AS A MOUNTING MEDIA*

LIONEL BENJAMIN, B.S., CHICAGO, ILL.

GUM dammar, when in solution with the various well-known solvents, has always been considered an ideal mount-material affording better definition of delicate detail than the commonly used Canada balsam, due to its light colored solution and low refractive index. In spite of these desirable qualities it has been little used for permanent mounts because it forms either macroscopic or microscopic granules which causes confusion when examined at a later date. It has a tendency to become acid, thereby affecting nuclear stains. The solution, upon standing, becomes cloudy and the dried film when deposited from a benzol or xylol solution is hard and brittle. No wonder that this resin has been relegated to the scrap heap.

Gum dammar has been used in the varnish and lacquer industries for many years and while considered a very desirable resin, it presented many problems before it could be used to give a satisfactory film. Varnishes were first made by dissolving the gum in an appropriate solvent and sold to the trade as a cheap substitute. Under these conditions the dried film had a tendency to become white, powdery, and brittle. The films would not withstand shock or friction which made them undesirable.

Chemically, gum dammar has been found to consist of dammarolic acid, alpha dammar resene, and beta dammar resene. The last named constituent being a waxy substance with a low tensile strength is less soluble in the ordinary solvents and has a tendency to crystallize out during the evaporation of the solvent. Many processes have been developed for separating this substance from the other two constituents,† which rely on the difference in solubility between beta dammar and alpha dammar combined with dammarolic acid. The resulting material after the separation has remarkable properties as a varnish gum.

The author has had occasion to prepare many dammar-xylol solutions and has always been confronted with the above difficulties. By taking advantage of the method of treatment used in the lacquer industry, the resulting resin gave very desirable films, had none of the defects found in the raw gum solution, and still retained its excellent optical properties.

*Received for publication, March 2, 1932.

†British Patent No. 209,701; March 15, 1928. German Patent No. 503,615; August 30, 1927.

METHOD OF PREPARATION

A good grade of clear Indian or Malayan dammar is put into solution in the following combination of solvents:

Dammar	450 Grams
Ethyl acetate	57 c.c.
Acetone	57 c.c.
Benzol	266 c.c.
Methyl alcohol	285 c.c.

First mix the solvents thoroughly and then add the gum crushed to about the size of a pea. With occasional shaking during a period of four or five days, the resin will be completely dissolved, leaving all débris and a white slimy stringy mass, the beta dammar, in the bottom of the flask. Allow this to settle and then filter the clear filtrate directly into an evaporating dish. Evaporate on a water-bath until the resin is hard and while still hot add an equal volume of xylol. The addition of the xylol to the hot or melted gum facilitates a solution readily. At this stage sodium bicarbonate in excess is added and the solution is stirred by a mechanical stirrer for a period of twenty-four hours to neutralize any free acidity. The excess sodium bicarbonate is allowed to settle and the clear filtrate is either decanted or poured through a filter. The gum solution is now evaporated on the water-bath to any consistency desired.

In the event that the heating process has darkened the resin solution, decolorizing may be effected by adding activated charcoal to the thin xylol solution, heating for several hours on the water-bath, replacing the evaporated solvent and again filtering.

The advantages of this process are that granules are not formed in the dried film, there is no acidity developed, the solution remains perfectly clear, the optical properties of the gum are not altered, and the resin does not dry too quickly, becoming hard and brittle.

DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

BILIRUBIN, Concentration and Precipitation of, in the Gall Bladder and Bile Ducts, Elton, N. W., and Deutsch, E. *Arch. Path.* 15: 818, 1933.

The purpose of this study was to determine whether any physiologic basis existed for the precipitation of bilirubin on preexisting nuclei.

In a study of the concentration of bilirubin in the gallbladders and bile ducts of twenty-three cats and nine dogs the most dilute specimens were obtained, not from the hepatic ducts after cholecystectomy, but from the gallbladders as they were refilling after postprandial evacuation, and the most concentrated specimens were secured from gallbladders after the animals had fasted for from twenty-four to one hundred and forty-four hours. Hepatic duct bile after cholecystectomy invariably yielded a higher bilirubin content and icteric index than the early refillings from the gallbladders.

The factor of bilirubin concentration for dogs was found to be 50.9, for cats, 40.4 and for both animals together 83.3. According to the work of Kalk and Schondube, the factor for either of these animals is appreciably less than that found for man.

The bilirubin icteric index ratio averages lower for gallbladder bile than for bile obtained from the hepatic ducts after cholecystectomy in these animals.

Correlation of the refractive index with the quantitative bilirubin or the color intensity of bile indicates that a critical concentration exists at which bilirubin tends to precipitate out of solution. When this critical concentration is exceeded, the density of bile at once attains its maximum, being constant thereafter in spite of continued concentration. These findings indicate that a limit of crystalloid concentration exists, affecting bilirubin, bile acid derivatives and cholesterol, and effective when the critical concentration is exceeded, and that their further concentration can be only as suspended colloids or undissolved crystals.

Studies on the concentration of bile during fasting showed that the maximum level of bilirubin is usually attained in the gallbladder within twenty-four hours, and that after this interval hepatic bile leaks into the duodenum. The density was found not to increase, even after six days of fasting, above the value attained in twenty-four hours.

The aqueous (direct) van den Bergh reaction on fresh bile simulated any of the various types of reactions described for icteric serums, including immediate blue violet and red reactions, slow and delayed reactions and the negative reaction.

Since gallstones are seldom found in the cat and the dog, the physiologic precipitation of bilirubin during its concentration in the normal gallbladders of these animals cannot be regarded as the exciting cause in the origin of biliary calculi, but affords a physiologic basis for deposition of the pigment on preexisting nuclei.

AGGLUTINATION, H & O following Typhoid Vaccination and in an Unselected Group of Individuals, Dulaney, A. D., Wickle, W. T., Stewart, R. L., Bayfield, J. D., Walker, J. K., and Preacher, A. B. *J. Immunol.* 24: 229, 1933.

From a study of 90 serums from vaccinated (TAB) individuals and 100 unselected Wassermann serums it is concluded that:

1. Typhoid vaccination stimulates the production of H agglutinins to high titers. O agglutinins are also stimulated, but show much lower titers.
2. O agglutination in serum dilutions of 1:100 was demonstrated in 26 per cent of all vaccinated serums and 11 per cent of a random group of individuals.
3. If O agglutination is to have diagnostic value in typhoid fever, higher dilutions of serum than those recommended by Felix (1:100) must be employed. The authors recommend dilutions of 1:500.

FECES, A Convenient Specimen Container, Frobisher, M. Am. J. Pub. Health 23: 851, 1933.

The outfit consists simply of a 2-ounce, wide-mouth glass bottle with a cork stopper. A wooden tongue blade is cut into halves and one end of each piece is whittled to a sharp, flat point which is thrust firmly into a cut in the narrow end of the cork, the cut in the cork having previously been made with a paring knife. The cork is then fitted into the bottle and the whole sterilized in the hot air oven at 170 C. for two hours.

A good grade of cork or a rubber stopper must be used in order to avoid leakage if pressure develops. If a preserving solution is used, sterilization may be accomplished in steam.

A slightly more expensive modification of this outfit may be made from sheet metal. The wooden paddle is replaced by a piece of metal, and this may be fastened with a few drops of solder (necessitating steam sterilization) to the inside of a metal clamp or screw cover, very much in the same manner as small brushes are supplied in cans of certain brands of automobile "touch up" paint. The possibility of bactericidal or bacteriostatic effects due to the metal must be taken into consideration before adopting such a device. Much will depend on the distance, time and temperatures involved in transporting the material to the laboratory. Both types of paddle can be used more than once. Metal paddles can be made spoon-shaped to facilitate the collection of liquid material.

In collecting the feces specimen the spatula always remains with the bottle, it is not touched by anyone and no disposal or esthetic problem arises.

TUBERCULOSIS: A Technique for Estimating the Number of Tubercle Bacilli in Sputum, Hughes, J. Am. Rev. Tuberc. 28: 279, 1933.

Preparation of Specimen and Smear.—One cubic centimeter of a 10 per cent solution of sodium hydroxide is pipetted into a test tube of 10 c.c. capacity, and 2 c.c. of sputum is added, along with three glass beads. The mouth of the test tube is flamed, and stoppered with a cork. The tube is then placed in a shaking machine in a horizontal position, and agitated. Because of the viscosity of sputum, pieces of ordinary glass tubing, 4 mm. in diameter and 25 cm. in length and graduated by a mark with a file to deliver 2 c.c., have been used instead of the usual type of pipette. Sputum can be readily drawn up into such a pipette by means of a Luer syringe attached to it by rubber tubing.

After being digested and shaken for thirty minutes the specimen is removed from the shaking machine. The following technic is used in making smears:

An area of 400 sq. mm. is marked off on the end of a one-inch microscopic slide by drawing with a diamond pencil a line 1.5 cm. from one end. This measurement introduces an error of less than 0.5 per cent. The slide is then cleansed by being placed overnight in a solution of alcohol, 97 c.c., and acetic acid, 3 c.c. By means of a standard loop, 3 mm. in diameter, made of platinum wire 0.4 mm. in thickness, sold by dealers in laboratory equipment, one loopful of serum used to fix the bacilli to the slide and one loopful of the digested sputum are mixed together on the slide, and are then spread in a uniform smear over the marked-off area of 400 sq. mm. The smear is dried in air, fixed by heat and stained by the usual Ziehl-Neelsen technic. Ten scattered oil-immersion fields are examined and the average number of bacilli per field is estimated. This average is then corrected for the dilution of the sputum by sodium hydroxide by multiplying the number of bacilli seen per field by the factor 1.5.

Since, in the present method, the 3 mm. loop used in making the smear delivers approximately 3.5 c.mm. of treated sputum, it is possible to estimate the number of bacilli in 1 c.mm. of sputum after calculating the average number of bacilli per microscopic field and the number of fields in the smear. This may be expressed by the following equation:

$$\text{Average number of bacilli seen per microscopic field} \times \frac{\text{Number of microscopic fields of smear}}{3.5} = \frac{\text{Number of bacilli in 1 c.mm. of untreated sputum}}{3.5}$$

In the microscope used for this work there were 25,000 fields in the area of the smear, but this figure will vary depending upon the size of the oil-immersion field of different microscopes. It can be readily determined for any microscope by calculating the diameter of the oil-immersion field by focusing on the rulings of a hemocytometer that are 0.05 mm. apart. In doing this it is necessary to use a No. 1 or No. 2 cover slip to cover the rulings, because the oil-immersion lens cannot be used with the heavier cover-slip provided with the hemocytometer.

By working out the equation for estimating the number of bacilli in 1 c.mm. the factor 10,714 was obtained, which, when multiplied by the average number of bacilli per oil-immersion field, gave the number of bacilli in 1 c.mm. of sputum.

RENAL FUNCTION: In Persons With One Kidney, Ellis, L. B., and Weiss, S. *Am. J. M. Sc.* 186: 242, 1933.

The renal function of 12 patients who had undergone unilateral nephrectomy was studied by urea and creatinin clearance, concentration and phenolsulphonephthalein tests. Nine of the patients were quite healthy, 2 had pyonephrosis of the remaining kidney and 1 had hypertension.

The 2 cases which were studied immediately after operation showed diminished values for the clearance and concentration tests. The tests on 7 other uncomplicated cases were normal in 2, and one or more of the tests were slightly abnormal in 5. The 3 patients with complications had marked impairment of renal function.

In the absence of complications, the renal function of persons with one kidney is not only adequate, but possesses a reserve capacity as well.

The observations confirm the value of urea and creatinin clearance tests in detecting early and quantitative reductions in glomerular function and of the concentration test as a measure of tubular reabsorptive power.

RENAL FUNCTION: Normal Variations in Renal Function Tests, etc., Ellis, L. B., and Weiss, S. *Am. J. M. Sc.* 186: 223, 1933.

On 12 normal subjects urea and creatinin clearance tests were performed and on 5 subjects dilution concentration tests were carried out. These studies were made to show the normal variations of each test and the effect of changes in one test on the others, and to correlate the results with the physiologic functions of the kidney which they measure.

The creatinin clearance test probably gives a close estimate of the absolute degree of glomerular filtration and the urea clearance provides a relative index of this function. Clinically, either test may be used.

The ability of the renal tubules to reabsorb fluid is best measured by a concentration test.

To attain as adequate an estimate as is possible by laboratory methods regarding the state of renal function, the tests mentioned together with an ordinary examination of the urine will suffice.

At best the information gained from these procedures merely supplements that obtained by the actual clinical observation of the patient.

PELLAGRA: A Chemical Peculiarity of Pellagra Blood (Rapid Iodin Decolorization), Campbell, C. H. *Am. J. M. Sc.* 186: 266, 1933.

Pellagrous blood reduces iodine solutions at a constantly greater rate than that of any other blood thus far examined. This phenomenon is made the basis of a test which promises to be of clinical value in the diagnosis of pellagra. Many pathologic conditions have not been examined, and it is possible that further work will disclose that other conditions simulating pellagra may give positive reactions. However, the phenomenon of increased rate of iodine decolorization by the erythrocytes in pellagrous blood may lead to fruitful information bearing on the etiology of pellagra, certain entities of avitaminosis and malnutrition.

Reagents.—

Alcohol-ether Mixture: A mixture of 3 volumes of 95 per cent ethyl alcohol and 4 volumes of ether (commercial or anesthetic ether may be used; chemically pure ether has not been tried).

Iodine Solution: Accurately prepared Lugol's solution (5 per cent iodine in 10 per cent potassium iodide).

Color Standards: Prepare a 3 per cent potassium dichromate solution and from this make the following dilutions: 1 to 5, 1 to 10, 1 to 20, 1 to 40, 1 to 80, 1 to 120, 1 to 240. Place these standards in a series of test tubes of the same internal diameter.

Procedure.—

Liquid Petrolatum. Five cubic centimeter samples of normal or nonpellagrous (control) and of suspected pellagrous venous blood are withdrawn and quickly introduced to 15 c.c. centrifuge tubes containing 5 c.c. of liquid petrolatum. The time of collection of each specimen must be recorded. As each sample is collected, the tube is stoppered and shaken very vigorously until the blood is defibrinated. This may best be accomplished by striking the stoppered end of the tube against the palm of the opposite hand. The specimens are then allowed to stand for thirty to forty-five minutes, after which they are again vigorously shaken and centrifuged at 1,000 revolutions per minute for 5 minutes. Before the second shaking it is advisable to remove the stoppers momentarily to permit the entrance of air for adequate oxygenation. When the tubes are removed from the centrifuge three distinct layers may be distinguished, namely, an upper layer of fibrin and oil, a middle layer of serum and a lower layer of erythrocytes, leucocytes, etc., which the author shall designate the erythrocytic layer. If any sample has not been properly defibrinated clots will be present in the lower layer. Such samples should be discarded. One cubic centimeter samples of the erythrocytic layers are now transferred by means of serum pipettes to test tubes of the same diameter as those of the standards. In the removal of these samples from the erythrocytic layer, care must be taken that no oil, fibrin or serum enters the pipette by capillary action as it passes through the two upper layers.

Exactly one hour after taking the venous blood specimen, add to the corresponding erythrocytic sample, slowly and without shaking, 5 c.c. of the alcohol-ether mixture and stopper the tube tightly. After the alcohol-ether mixture has been added to all samples, let them stand for approximately 6 hours at room temperature (25° to 30° C.). At the end of this time add in rapid succession to each tube by means of an accurate micro pipette (Folin micro blood pipette or Kahn serologic pipette) a 0.1 c.c. portion of the iodine solution. Mix gently and replace the stoppers.

BLOOD: A Study of a Lymphocytic Hemogram, Reich, C., and Reich, E. Am. J. M. Sc. 186: 278, 1933.

A lymphocytic hemogram has been studied, using basophilia of the cytoplasm as a criterion of the age of the lymphocytes.

The lymphocytic formula is stable in health, but is more labile than the Schilling index, and cannot be used to gauge the severity of an infection. Its shift to the left in infections nevertheless indicates that the lymphocytes take an active part in combating these conditions.

The lability of the lymphocytic index makes it valuable in detecting minor infections which do not disturb the more stable Schilling index.

The lymphocytic index is superior to the Schilling in guarding the progress of convalescence, and a patient should not be regarded as entirely well until the lymphocytic formula has returned approximately to normal.

Analysis of the experimental data shows that there is a fairly constant lymphocytic formula for normals. For adults this can be expressed as Y forms, 5 per cent; M forms, 50 per cent; O forms, 45 per cent. Variations occur in this formula under different conditions, and we can, therefore, speak of a shift to the left or to the right of the lymphocytic index, depending upon whether the number of younger forms is greater or less than normal.

A comparison with the Schilling index in each case shows that the two do not run parallel. The lymphocytic index is not as stable as the Schilling and will shift to the left just as easily in a mild as in an acute infection. Even though the lymphocytic formula cannot be used to gauge the severity of an infection, its shift to the left in these conditions nevertheless indicates that lymphocytes take an active part in combating bacterial invasion. This is seen by the increase in Y and M forms and the decrease in O forms in practically all cases of infection.

The lability of the lymphocytic hemogram makes it valuable in the detection of minor infections which do not disturb the more stable Schilling index. Interesting and confirmatory evidence for using basophilia as a criterion of the age of lymphocytes is seen in the study of the lymphatic leucemias. The marked increase in the proportion of Y and M forms in these cases represents the well-known hyperactivity of the lymphatic system in these diseases. In the myeloid leucemias there is also an increase in lymphocytic activity and a shift of the index to the left.

It is also of interest to note that, according to the lymphocytic index, most patients are not entirely well on being discharged from the hospital and that the period of convalescence is probably much longer than usually expected. A patient should not be regarded as entirely recovered from an infection until the lymphocytic formula has returned to normal.

Technic.—White and differential counts were done for each observation. The total white counts were done with carefully standardized pipettes, and the films were made on slides, care being taken to keep them "rim free." The stain used was Wiseman's Wright-Giemsa. An average of 200 leucocytes was counted and the lymphocytes were divided into three classes: Y (young), M (medium), and O (old) forms, according to the degree of basophilia of their cytoplasm. The Y forms have a deep blue cytoplasm, the M forms moderately blue and the O forms are faintly blue or colorless, and usually show azure granules in the cytoplasm, although the M forms occasionally show them too. A little practice with the above technic will make the three divisions clear. It is necessary, however, that the lymphocytes be examined in those parts of the film in which the red cells do not overlie, as in the thick portions of the film the lymphocytes are likely to overstain. The total number of lymphocytes is noted as well as the number of Y, M and O forms, and the percentages of each are then easily calculated, the procedure being similar to that followed in enumerating the different forms of polymorphonuclears when doing the Schilling index. When the total number of lymphocytes is low it is best to count 300 to 500 white cells to insure more accurate results. The polymorphonuclear leucocytes were tabulated according to the Schilling method in each instance in order to compare the granulocytic and lymphocytic indices.

RENAL FUNCTION: The Fractional Phenolsulphonephthalein Test in Bright's Disease, Chapman, E. M., and Walsted, J. A. *Am. J. M. Sc.* 186: 223, 1933.

The fractional method of estimating the elimination of phenolsulphonephthalein (15, 30, 60 and 120 minutes) has been studied in the past two years in 20 normal subjects and a large number of patients with suspected renal disease.

The authors have found that in Bright's disease the fractional test may show evidence of impaired renal function when the test as usually done, with hourly collections, is interpreted as normal.

This fractional test is quite as informative as the urea clearance test and reflects the diminishing function in progressive kidney disease.

Since it is easier to perform, it is the method of choice for routine clinical work.

BLOOD: The Neutrophil in Pernicious Anemia, Heck, F. J., and Watkins, C. H. *Am. J. Clin. Path.* 3: 263, 1933.

Fifty cases of pernicious anemia, in all of which there was achlorhydria, have been studied with reference to the lobulation of the neutrophil. Increased segmentation in the neutrophil is the rule, although cases do occur in which there is a left shift and absence of the hypersegmented neutrophil.

In three cases in which there were morphologic changes of pernicious anemia in the presence of adequate quantities of free hydrochloric acid, but in which other characteristic symptoms of pernicious anemia were absent, no essential differences could be found from the former group.

There is no invariably pathognomonic blood picture of pernicious anemia, since the same changes may be demonstrated in sprue and occasionally in an indeterminate group of anemias.

SPIROCHETA PALLIDA. A New Method of Staining (Su Di Un Nuovo Metodo Di Colorazione Del Treponema Pallidum), Pinetti, D. Diagn. E. Techn. Di Lab. 4: 205, 1933.

Pinetti has had excellent results with the modification of Romby's method which is described below:

Reagents.—

A. Acetic Copper Solution:

Chloride of copper	gr. (gm?) 1
Acetate of copper	gr. (gm?) 1
Acetic acid, glacial	15 c.c.

Dissolve the copper salts "as far as possible" in cold distilled water (volume not stated) with frequent shaking and allow to stand 30 minutes. Then heat to boiling and allow to cool, when the acetic acid is added. Filter twice through filter paper and keep in a well-stoppered dark-colored bottle.

If turbidity develops in the solution on standing the clear, emerald-green color can be restored by the addition of a few drops of glacial acetic acid.

B. Fixing Solution:

Osmic acid	gr. (gm?) 1
Distilled water	400 c.c.

C. Staining Solution:

Freshly prepared carbolfuchsin (Ziehl Neelson).

Method.—

1. Cover the smear with a freshly prepared mixture of equal parts of A and B and allow to act for ten minutes. If necessary, add more solution so that the entire surface of the slide remains covered.

2. Pour off the solution and drain.

3. Without washing, cover with the stain and allow to act for five minutes.

In a properly stained slide the treponema are seen as violet red on a rose-colored background. Spirilla, and other organisms are deep red. A deeply stained background indicates an error of technic or in the preparation of the reagents.

Equally good results may be had by using, instead of carbolfuchsin, the stain below:

Victoria blue (Gruhler, R4)	gr. (gm?) 1
Thymol	gr. (gm?) 0.20
Methyl alcohol	30 c.c.
Distilled water	70 c.c.

With this stain, applied as above described, the treponema are an intense blue black, their delicate structure being exceptionally well seen.

The background is clear, precipitate being rare.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

Red Blood Cell Diameters*

See Editorial in this issue.

Manual of Urology†

THE purpose of this manual is to present the fundamentals of urology so that they may be easily grasped by the student approaching this subject.

The arrangement of the subject matter is designed to emphasize the etiological factors concerning the disease in question in the discussion of which, as the book is intended for the student, only generally recognized conclusions are presented.

To those who are desirous of obtaining a fundamental groundwork in urology upon which to erect a comprehensive knowledge of the subject this book can be recommended as eminently suitable for the purpose.

Blood Pictures‡

THIS small volume, addressed to the practitioner, has for its purpose the presentation of simpler methods of hematological examination, followed by brief résumés of the blood pictures in disease and their interpretation.

The book is succinct in style and serves, as the title indicates, as an introduction to the subject.

This, the third edition, has been revised in keeping with the advances made in this subject.

The Common Cold§

THIS, the Eighth Volume of the Annals of The Pickett-Thomson Research Laboratory, is devoted to a comprehensive discussion of the common cold with special reference to the part played by streptococci, pneumococci, and other organisms.

The publications from this laboratory need no introduction and it is almost unnecessary to say that the present volume is in keeping with and worthy of the standard set by its predecessors.

As is now well recognized, the common cold constitutes one of the most—if not the most—important factors in the morbidity and mortality rates of the civilized world and, because of its economic importance as a cause of physical wastage and inefficiency, has become the subject of concerted and intensive study.

Erythrocyte Diameters

FOLLOWING the development of the modern methods in the study and treatment of pernicious anemia, interest in erythrocytology has been widely awakened. Smears that formerly would have been classed as indicative of secondary anemia have occasionally been found to be those of primary anemia. Smears that most pathologists would interpret as characteristic of pernicious anemia have been found to occur in patients that do not have primary anemia. There appears to be a distinct group of this second class. Not infrequently one observes blood smears with clear-cut macrocytosis, with or without anemia, which are definitely not associated with pernicious anemia. As a consequence the measurement of erythrocyte diameters not infrequently becomes a matter of diagnostic laboratory routine.

Attempts to measure red cell diameters are by no means new. While some of the earlier methods were crude and the conclusions were not altogether cor-

The present volume, because of its comprehensive review and summary of the work thus far done, ranks as a study of first importance and may well be read by all who are interested in this subject.

Starting with a review of the structure and physiology of the nose and nasal sinuses, the researches concerned with the bacteriological flora of the healthy nose, nasopharynx, mouth, trachea, bronchi, and lung alveoli are next described as determined not only by the investigations of the authors, but also as reported in the literature of the world.

The plurality or nonplurality of colds as a disease, the relationship of the common cold to influenza, and the noncontagious colds are next considered, followed by exhaustive studies of the rôle of various specific organisms as causative agents. Subsequent chapters discuss various predisposing factors, complications, treatment and prevention so that, all in all, the volume is practically encyclopedic in its handling of the subject.

The authors' views deserve careful consideration and can only briefly be summarized here.

They are not convinced that the common cold is a definite single disease but regard it as a group of diseases, arising from varied causes. They recognize, hence, bacterial colds, allergic colds, and possibly virus colds. While not unmindful of the work done concerning the part played by a filter-passing virus as an etiological agent of colds, they believe that to regard all colds as so caused is carrying the theory too far and casting aside without warrant the work proving the important relation of bacteria.

They are convinced that the commonest bacterial variety of cold is the pneumococcal, followed by the streptococcal and streptopneumococcal. Of importance, also, are the colds due to invasion by Pfeiffer's bacillus, and *M. catarrhalis*, other bacterial colds being infrequent. They comment, also, that it has not yet been shown that filtrable forms of these bacteria may not be the answer to the filter-passing virus theory.

It is impossible, in the space available for review, to convey more than a mere outline of the ground covered by this most comprehensive and valuable report which should be available to all laboratory workers and may well be read with profit by the physician at large.

The format and the excellent microphotographic illustrations will be familiar to those who have seen the previous volumes of this series.

As this reviewer has previously said, it seems a pity that these volumes of such value should not have a more durable covering than paper, for they are sure to be well read and frequently consulted.

Erythrocyte Diameters

FOLLOWING the development of the modern methods in the study and treatment of pernicious anemia, interest in erythrocytology has been widely awakened. Smears that formerly would have been classed as indicative of secondary anemia have occasionally been found to be those of primary anemia. Smears that most pathologists would interpret as characteristic of pernicious anemia have been found to occur in patients that do not have primary anemia. There appears to be a distinct group of this second class. Not infrequently one observes blood smears with clear-cut macrocytosis, with or without anemia, which are definitely not associated with pernicious anemia. As a consequence the measurement of erythrocyte diameters not infrequently becomes a matter of diagnostic laboratory routine.

Attempts to measure red cell diameters are by no means new. While some of the earlier methods were crude and the conclusions were not altogether cor-

rect, it is indeed surprising how accurate they were, considering the methods available. Cecil Price-Jones in his very informative monograph on *Red Blood Cell Diameters* reviews the history of this phase of hemocytometry in conjunction with his presentation of his own very detailed studies of the measurements of red cells in disease and in health.

As long ago as 1673, Leeuwenhoek attempted measurement by the very crude method of placing minute grains of sand in a row, one inch long, all grains being as nearly as possible the same size. By counting the number of grains in contact to make an inch, he was able to estimate the diameter of one grain in terms of fraction of an inch. With this grain for comparison he attempted to measure red cell diameters. Later investigators substituted lycopodium spores with a mean diameter of $\frac{1}{940}$ of an inch for the sand grains.

Jurin in 1718 twisted fibers of silk or hair around a pin, with the successive twists in close contact; counted, under the microscope, the number of coils per unit measure, thereby determining the mean thickness of the hair. A segment of the hair was then compared with erythrocytes. This method was not altogether satisfactory since the hairs and fibers varied in thickness. He calculated the erythrocyte diameters in one series as averaging 7.75 microns, and in another series 12.5 microns.

de Senae in 1749 compared red cell diameters with a standard line, concluding, first that they measured 7.22 microns, later 7.69. Hewson in his famous work on the blood (1770) makes no definite estimate of the size of the erythrocytes but does state that the size varies in different animals and sometimes in the same animal, and again at different periods of life. This was particularly true in the chick.

Prevost and Dumas (1821) employed binocular vision, observing the cells through the microscope with one eye while their image was superimposed upon a scale placed next to the microscope and seen with the other eye, with accommodation relaxed. They estimated the mean diameter as 6.6 micra. Young in 1823 attempted measurement by comparing the luminous halo surrounding the erythrocytes with that surrounding other objects of known diameter, and of approximately the same size, concluding that the diameter of the human red corpuscle was between 5 and 6 microns.

Lister, the father of Lord Lister, and his associate Hodgkin, using Amici's camera lucida (1827) selected 8 microns as the correct size. Gulliver in 1846, using a micrometer eyepiece found the diameter of human red cells to average 7.61 microns. He found that of the elephant, 9.1; the whale 8.03; the musk deer 2.02; the cat 5.6; and dog 7.05.

Price-Jones using a projection apparatus adjusted for a magnification of 1,000 (1910) measured the resultant images with a millimeter scale, recording these figures directly in terms of microns. He found the mean diameter in healthy persons based upon measurement of 10,000 cells to be 7.21 microns, with a mean range from 6.96 to 7.49 (1922). In a later series based upon measurement of 50,000 red cells, the normal diameters were found to range from 4.75 to 9.50 with a mean diameter of 7.202, a standard deviation of 0.487 and a coefficient of variation of 6.325 per cent.

In measuring erythrocyte diameters Price-Jones emphasizes the need for a standard and unvarying technic in preparation. His technic is briefly as follows: A thin spread, air dried, fixed and stained with Jenner stain for two minutes; washing with distilled water and drying, followed by a two-minute super staining with weak aqueous solution of eosin. Deviations from this standard procedure were found to sometimes produce changes in the mean diameters. He prefers counts of 500 cells, with a minimal number compatible with reasonable accuracy of 200. Largest and smallest diameters are taken for each cell, the diameter value of the cell being the average of these two. The arithmetic mean, the standard deviation, and coefficient of variation are then calculated mathematically.¹

Price-Jones finds, even in normal individuals that there is a distinct diurnal variation in red cell diameters, probably dependent upon the hydrogen ion concentration. There is a gradual increase in size during the day, with a diminution during sleep. The variation may amount sometimes to as much as 0.6 microns. Gentle exercise has no apparent influence but violent exercise increases diameters. Nevertheless rest in bed throughout twenty-four-hour periods does not abolish the diurnal variations. The increase in size following violent exercise may amount to as much as 0.6 microns.

The observation that local cyanosis increases diameters, anywhere up to 0.4 microns, emphasizes the need for obtaining specimens without the use of a tourniquet. Cells in venous blood are larger than those in arterial blood.

These variations in size appear all to be due to changes in hydrogen ion concentration, the swelling being associated with a decrease of alkalinity. It has been shown both in vitro and in vivo that an increase in concentration of lactic acid or of carbon dioxide causes swelling. The washing of CO₂ out of the blood by forced breathing was found to diminish the mean diameter by 0.5 microns. Discontinuance of forced breathing brought a rapid restoration to normal diameters. There is evidence that the blood is more alkaline during sleep than in the daytime.

Pulmonary emphysema, especially when associated with some degree of cyanosis is accompanied by macrocytosis, the mean diameters ranging from 7.33 to 8.17 with a mean diameter for the series of 7.69. On the basis of the same considerations it seems entirely possible that certain chemical poisonings should produce a macrocytic anemia suggestive on microscopic examination of pernicious anemia, but in no way connected with the latter disease. Indeed Beek² has described a blood picture following low grade chronic carbon monoxide poisoning, almost indistinguishable from that of pernicious anemia.

The mean diameter following hemorrhage is lower than the mean for healthy persons, averaging 6.879 with a range from 6.3 to 7.225. The distribution curve is shifted to the left of the healthy curve. There is greater variation in the curves, the coefficient of variation averaging 10 per cent, due presumably to the mixture of two types of cells, the mature red cells and smaller, newly formed cells which have been poured into the circulation as a result of sudden overstimulation of the marrow.

In pernicious anemia, Price-Jones found a variation in diameters from 3.75 to 13.0, with a mean diameter of 8.31, over one micron greater than the

average for healthy red cells. The coefficient of variation was as high as 16.3 per cent and the excess of large cells resulted in a megalocytosis of 40.4 per cent. Microcytosis was also present, in about 75 per cent of the cases.

The mean cells of normal persons show a curve of variation which is sharply pointed and quite symmetrical. That for pernicious anemia has a much broader base and is decidedly irregular, usually asymmetrical. This suggests a heterogeneous population of red cells. It seems probable that in the blood of pernicious anemia there are at least three classes of red cells: large cells derived from megaloblasts which have failed to mature due to the lack of the specific intrinsic liver factor; normal size cells from what bone marrow is still reacting normally; and small cells which owe their origin to the same causes which are active in simple acute hemorrhage, that is extra stimulation of bone marrow caused by abnormal destruction of erythrocytes. That these three classes actually exist is further suggested by the observation that the degree of anisocytosis varies directly with the degree of anemia, while the red cell diameters are independent of the degree of the anemia. It would appear that the disease is responsible for the macrocytosis and is associated with the absence of the intrinsic liver factor, but that the presence of microcytes is directly due to bone marrow stimulation resulting from the anemia. Following liver treatment the macrocytosis becomes less pronounced. Indeed in many cases the mean diameter returns to normal.

The mean diameter in microcytic anemia, the chlorotic anemia occurring particularly in women during the child-bearing period and often associated with gastric subacidity or anaecidity, was found by Price-Jones to be 6.48 microns with a range from 6.2 to 6.7 microns.

The observations on red cell diameters reviewed above indicate not only the large amount of work which has been done in this field but also the possibilities for future contributions which may be made by those who in their routine work will recognize the apparent slight deviations from normal which will bear further quantitative study and which may lead to a clearer understanding of the subject.

CLINICAL AND EXPERIMENTAL

SURGICAL MAGGOTS IN THE TREATMENT OF INFECTED WOUNDS: RECENT APPARATUS AND METHODS IN MAGGOT PRODUCTION AND RESEARCH*

W. ROBINSON, PH.D., AND S. W. SIMMONS, A.M., WASHINGTON, D. C.

A PREVIOUS article in this JOURNAL³ and a recent circular of the U. S. Bureau of Entomology⁴ describe the biology of the blow flies and the production of sterile maggots. The present discussion deals with some recent devices and methods which have been found useful in maggot culture and research.

Culture Bottles for Sterile Maggots.—Aseptic rearing of maggots is carried on best in small lots. The principal reason for this is that if contamination is detected the loss in discarding that lot is correspondingly less when a small culture is used. Lots containing from 700 to 1,000 seem to be preferable.

For a culture of that size a wide mouth specimen bottle, Fig. 1 B, makes a simple and useful container. Shoulders are almost absent in this type of bottle which facilitates the removal of the maggots and food at the time of implantation. This is a stock bottle 3 inches high, 1½ inches wide with a mouth opening of 1¼ inches. It is made of heavy glass and is quite inexpensive. Shell vials of similar dimensions have been found useful also, but as they do not appear to be carried in stock by supply houses they have to be made up by a glass blower. Satisfactory results have also been obtained with the Naples staining jar, Fig. 1 A. It is made of heavy glass and has a base which prevents

Received for publication, March 16, 1933.

tipping. It costs about the same as the shell vial, both of which are more expensive than the stock wide mouth bottle.*

When being prepared for use, the containers are plugged with gauze-covered cotton and sterilized in a hot-air oven at 150-160° C. for one hour. The food (described later) is then added and autoclaved. Wire letter baskets are convenient for holding the containers.

Rearing Cage for Brood Larvae.—To replace fly colonies when egg production begins to decline, a certain proportion of maggots must be reared through to the adult stage. This process is somewhat different from production of sterile maggots and requires a different container. The biology involved in maggot rearing is discussed in the earlier article.³ By far the most satis-

Fig. 1.—Food containers for culture of sterile maggots: A, Naples jar; B, specimen bottle.

factory cage for brood larvae, which this laboratory has used, is the double container illustrated in Fig. 2. It consists of an outer cage enclosing a food container and sand for pupation. It is a very simple device and easily obtainable. The outer cage may be a large glass beaker, a dressing jar, or preferably a commercial oiled-fiber can, as shown in the illustration, one-half gallon size, 5½ inches high and 5½ inches in diameter. The fiber cans are quite inexpensive and are useful for other purposes in the laboratory.

When the cage is being prepared for use, the material used for the migrating larvae (discussed later) is placed in the outer container. The inner one is then introduced. This may be similar to the outer one, but of much smaller size. If the fiber can is used, the inner one may be either a half-pint or pint size, preferably the former. With the meat and eggs added, this container is

*In case of uncertainty as to where to purchase these or other special articles mentioned, the Bureau of Entomology will, upon request, supply the necessary information.

placed within the cage and left uncovered. The outer cage, however, should be covered, to exclude parasites, which may become troublesome. Gases form during larval feeding and, if allowed to accumulate within the cage, tend to cause premature migration. Some ventilation is therefore necessary. A layer of cheesecloth makes a suitable covering, or, if observation is desired, perforated cellophane will be found convenient. If the fiber can is used, the cover may easily be attached by pressing the circular top out of the lid and using the rim as a collar to keep the cloth or cellophane in place.

With the closed container as described, the rearing of larvae for propagation requires but little attention. It should be noted, however, that an abundance of meat is necessary. Undernourished larvae will pupate but will develop into small flies with poor egg-laying capacity. The larvae will feed until full grown and then migrate without further care. Because of their compactness, these cages occupy little space within the incubator.

Fig. 2.—Rearing cage for brood larvae. One sectioned to show construction, and the other ready for use.

Material for Pupation of Larvae.—When the larvae begin migrating from their food, they must be provided with a suitable place for pupation. When this is supplied the maggots will enter at once; otherwise they will wander and possibly escape. Various materials, such as sand, shavings, sawdust, ground cork, and the folds of cheesecloth, have been used; but fine, clean sand is recommended by this laboratory. When sand is used it is very easy to recover pupae, when desired, by sifting. It is also available at most laboratories. About one inch of sand placed in the bottom of the outer container is sufficient.

The Water Fountain.—Where honey-yeast mixture is used as food for the adult flies, it will be noted that the mixture tends to dry out over hot weekends. Granulated sugar is an excellent substitute at such times; but when used, a supply of water must be provided. To avoid drowning of the flies, water is best supplied by means of a fountain. Several kinds have been tried, but the most satisfactory one is the type described by Miller.² It consists of a 50 c.c. beaker placed inverted upon a layer of filter paper in a Petri dish. The

lip of the beaker ensures a sufficient flow of water to keep the paper moist. Such a fountain will provide enough water for a cage of 150 flies for three or four days.

Determination of Number of Eggs.—In research in the field of maggot production it is sometimes necessary to know the number of eggs laid or to isolate a definite number. The eggs are usually laid in masses and remain attached to one another because of their mucoid surface. Estimating the number by the size of the clump has been found to be unreliable; on the other hand, counting individual eggs after separation is very tedious.

A method of determining the number by weight has been found satisfactory. A standard or constant was obtained by taking numerous egg-masses periodically from different colonies, weighing them, and separating and counting the eggs. In this way it was found that on the average 9.9 eggs weigh one milligram. This average may vary slightly from time to time and should be checked.

To make a determination, therefore, of the number of eggs in any clump it is necessary only to weigh the mass accurately and multiply the number of milligrams by the constant. An analytical balance should be used, preferably one of the modern type which permits rapid adjustment in milligrams. The eggs may be conveniently weighed upon a glass or tin foil plate.

Egg Viability Tests.—In the production of sterile maggots it will be found that a certain proportion of the eggs frequently fails to hatch. While this may not be important in routine maggot production, it is of significance in research, and determination of the percentage of failure under various conditions is sometimes necessary. The following method of determining viability has given good results.

Sterilized larval food is used in the test because the formation of molds or colonies of bacteria over the eggs prevents hatching. A few cubic centimeters of 1 per cent solution of plain agar in water is poured into the Naples jars or shell vials previously described. Small pieces of raw liver are then dropped into the agar. The pulverized liver mixture of Buchman and Blair¹ also gives good results. The containers are then plugged and autoclaved. The eggs used in the viability tests cannot be sterilized, as that would introduce another factor affecting hatch. A known number of eggs, probably 200 to 300, are placed without injury upon two thicknesses of wet sterile absorbent gauze about 2 inches square and transferred aseptically to the inside of the jar just above the food. Excess water should be previously drained off, otherwise the water contaminated by the unsterilized eggs might inoculate the food. The cultures are then placed in the incubator for hatching of the eggs.

When the larvae have fed for three days the food is usually sufficiently liquefied, and the maggots are large enough to strain out. Water is then poured into the jars and left for a few minutes, immersion separating the larvae rapidly from the food. If the maggots are numerous and active the water should be cold to reduce their activity while being counted. If their number is small, the food will not be sufficiently liquefied and warm water is preferable. The contents of the jars are then stirred, strained through a fine

wire sieve over a beaker, and transferred to a Petri dish. Estimation of number has been found especially unreliable, and determination of number by actual count appears essential. A hand counter has proved very useful in making counts.

Elimination of Odor.—Disagreeable odors develop readily during maggot production and research, but if sufficient care is taken they can be prevented from becoming noticeable in the laboratory. The exhaust draft recommended for the larval cabinet³ will prevent leakage of odors into the room. The ordinary type of household fan, however, placed within the cabinet to force air up a ventilator is usually not satisfactory. An exhaust fan installed on the ventilator line to draw off the odors is more preferable and is not expensive.

Residue from the feeding of brood larvae is especially offensive and should be promptly destroyed. Each laboratory will probably have certain facilities for waste removal. A very satisfactory method is to use a paper bag in a covered receptacle such as a large dressing jar or a can and to keep this in the larval cabinet or in a chemical hood. At the end of each day the bag is burned. An incinerator or steam generating plant is usually available to the laboratory.

HYPOLUCOCYTIC ANGINA*

AN UNUSUAL FORM OF INFECTIOUS LEUCOPENIA

NATHAN ROSENTHAL, M.D., AND MAURICE A. KUGEL, M.D., NEW YORK, N. Y.

THIS syndrome is clinically similar to agranulocytic angina in its sudden onset, high fever, prostration, and the presence of necrotic ulcerations of the mucous membranes, particularly in the oropharynx. The blood count, however, differs from that usually found in agranulocytic angina, as well as from other forms of leucopenia, in that there is in addition to the profound leucopenia a relative polynucleosis of the nonsegmented neutrophils. In all cases of agranulocytic angina reported in the literature, the leucopenia has been the result of a marked diminution or absence of the polymorphonuclear neutrophils, which in fatal cases usually have disappeared completely from the circulating blood as well as from the bone marrow (Schultz¹).

Ulcerations of the mucous membranes and an extreme leucopenia may occasionally be present in other conditions simulating agranulocytic angina, notably in leucopenic leukemia, aplastic anemia, benzol and arsphenamine poisoning, and poisoning from radium or x-rays. In these conditions, however, marked alterations are also found in the hemoglobin, red blood cells or platelets, and at times immature myeloid cells are present in the peripheral blood. Ulcerations in the oropharynx, and rarely leucopenia may likewise occur at the onset of infectious mononucleosis (McKinlay and Downey²).

The three cases to be reported in this paper, although clinically resembling agranulocytic angina, showed a relative polynucleosis (nonsegmented neutrophils), associated with a profound leucopenia, with a more or less parallel reduction in the lymphocytes and monocytes. The red blood cells and platelets remained unaffected.

Detailed reports of these cases follow:

CASE 1.—I. K., female, aged fifty-two, married; admitted to private pavilion of Mount Sinai Hospital (Service of Dr. A. A. Epstein), December 19, 1923.

Previous History.—Following an operation for fibroids eleven years previously, the patient developed persistent and irregular pain in the epigastrium, which became severe while eating, but subsided somewhat about two hours after the ingestion of food. From time to time there was considerable nausea, but no vomiting. The appetite was poor; the diet consisted chiefly of crackers and tea. The bowels were constipated. The patient entered the hospital for an exploratory laparotomy.

Examination on Admission.—The patient was well developed. The mouth, throat, heart, and lungs were normal. The liver and spleen were not palpable. There was slight tenderness in the epigastrium. The urine showed a faint trace of albumin and occasional hyaline casts.

*From the Wards and Laboratories of the Mount Sinai Hospital.
Received for publication, January 6, 1923.

The blood examination showed a slight leucopenia:

Hemoglobin	85 per cent
Red blood cells	4,000,000
White blood cells	4,500
Polymorphonuclear neutrophiles	55 per cent
Lymphocytes	45 per cent

Course and Treatment.—An exploratory laparotomy was performed by Dr. A. A. Berg on Dec. 26, 1928. A diverticulum on the posterior wall of the duodenum was found. Otherwise, no other abnormality was noted. Following the operation, the temperature rose to 101.4° F. and remained around that level for two weeks.

About one week after the operation (Jan. 2, 1929), patient complained of a sore tongue and considerable pain on swallowing. Extensive ulcerations were found not only on the tongue, but also on the tonsils, uvula, pillars of the fauces, and on the hard and soft palates.

Fig. 1.—Nonsegmented neutrophiles in the peripheral blood showing "toxic" granules in the cytoplasm.

These were covered with yellowish membranes, easily removed without bleeding. Cultures of the ulcerations were negative for diphtheria bacilli and smears showed numerous streptococci and bacilli; and few spirilli. The patient became progressively weaker, as the condition of the mouth and throat did not respond to local treatment. Transfusion (500 c.c.) was followed by temporary improvement.

Three days later (Jan. 5, 1929), as the prostration, fever (104° F.), and oropharyngeal necroses became pronounced, the clinical symptoms suggested agranulocytic angina. The blood picture was compatible with this diagnosis, with the exception of the differential count. There was a relative increase in the percentage of the nonsegmented neutrophiles (the staff and young cells of the Schilling hemogram), associated with a profound leucopenia (Table I).

The neutrophiles, both segmented and nonsegmented, presented severe toxic changes (Fig. 1) in the cytoplasm. These consisted of the appearances of coarse granules and vacuolization. All the neutrophiles in this case showed such toxic changes as well as anisocytosis and poikilocytosis.

These abnormal blood changes persisted (Table I).

TABLE I

CASE 1

	JAN. 5, 1929	JAN. 6, 1929	JAN. 7, 1929 BEFORE R'ADIO- THERAPY	JAN. 7, 1929 6 HOURS AFTER R'ADIOTHERAPY
Hemoglobin	70%	74%	70%	
Red blood cells	3,400,000	3,800,000	4,000,000	
White blood cells	2,200	900	1,000	1,600
Platelets	450,000	430,000	240,000	
Polymorphonuclear nonseg- mented cells	52%	65%	44%	57%
Polymorphonuclear segmented cells	5%	2%	5%	8%
Lymphocytes	35%	26%	40%	29%
Monocytes	4%	4%	7%	4%
Plasma cells				1%
Macrophages			1%	
Myelocytes neutrophilic	4%	2%	3%	
Degenerative index	100%	100%	100%	100%

Comment.—The severe leucopenia associated with a high percentage of nonsegmented neutrophils in itself was an unfavorable prognostic sign. The number of neutrophils with toxic granules in the cytoplasm (Fig. 1) was very high (100 per cent). Such cytoplasmic toxic degeneration has been previously noted by Gloor,³ Mommensen and others.⁴ The quantitative measure of these pathologic neutrophils is obtained by dividing their number by the total number of neutrophils. This has been previously designated by us⁵ as the *degenerative index*. The persistence of a degenerative index of 100 usually indicates an unfavorable prognosis. The rapid increase of the degenerative index is usually associated with an unfavorable outcome. The index, therefore, may be regarded as a valuable aid in prognosis.

CASE 2.—R. C., female, aged sixty-two, admitted to Mount Sinai Hospital (Medical service of Dr. George Baehr), July 8, 1930, as a case of agranulocytic angina.

Previous History.—For six years preceding, the patient's complaints were chiefly cardiac, dyspnea, palpitation, and precordial pains.

Present Illness.—Six days previous to admission, there was generalized abdominal pain and diarrhea, followed by fever, progressive weakness, angina, and increasing dysphagia. Four days previously, swelling of the neck and parotid regions developed.

TABLE II

CASE 2

	JULY 8, 1930	JULY 9, 1930	JULY 10, 1930	JULY 11, 1930	JULY 12, 1930	JULY 13, 1930
White blood cells	1,800	2,200	11,600	10,000	9,600	19,900
Polymorphonuclear non- segmented cells	39%	44%	54%	50%	50%	60%
Polymorphonuclear seg- mented cells	10%	13%	11%	30%	39%	12%
Lymphocytes	33%	30%	21%	6%	9%	16%
Monocytes	13%	1%	12%	10%	2%	11%
Myelocytes	5%	6%	2%	4%		1%
Degenerative index	100%	100%	100%	100%	100%	100%

Examination on Admission.—The patient was obese, flushed, toxic in appearance, and somewhat stuporous. Several lesions resembling pustules were present on the skin. The mucous membrane of the mouth was dry, glazed and reddened; a large necrotic black slough was adherent to the palate and extended to the pillars of the fauces and the posterior pharyngeal wall. Tender swellings were found in both submaxillary regions and over the

left parotid glands. There was slight rigidity of the neck. Heart sounds were irregular and of poor quality. Breathing was stertorous.

Course and Treatment.—The clinical course was suggestive of agranulocytic angina. The blood picture, however, showed a white cell count of 1,300 with 49 per cent polymorphonuclear neutrophils, and 39 per cent nonsegmented cells (Table II); the hemoglobin, red blood cells, and platelets were normal. Blood cultures, taken on two occasions, were negative. All of the neutrophils contained toxic granules (degenerative index 100).

Signs of myocardial failure developed and on two occasions pulmonary edema, which subsided with medication (atropine and adrenalin). There was a transitory improvement for a few days after a blood transfusion (500 c.c.). The ulcerations and leucopenia both subsided. The white cells increased rapidly (two days) to 11,600, with 65 per cent polymorphonuclear neutrophils when the patient developed a right suppurative parotitis. Following this, the condition became considerably worse with signs of pneumonia and a rise in temperature to 105.8° F. and death ensued.

Fig. 2.—Bone marrow of Case 2. Note the hyperplastic bone marrow with many mature and immature myeloid cells

Comment.—In this case the rise of the white blood cells from 1,800 to 10,000 after two days in the hospital would ordinarily be considered a favorable sign. In following the blood picture daily (Table II), two signs were significant: (1) the nonsegmented neutrophils steadily rose from 39 per cent to 60 per cent; and (2) the degenerative index persisted at 100 per cent throughout the course of the disease. Although some of the hematologic findings were suggestive of apparent recovery, the severe complications (parotitis and pneumonia) led to a fatal outcome as was prognosticated by other blood changes, i.e., the high degenerative index, and the progressive increase of the nonsegmented neutrophils.

CASE 3.—J. J., male, aged thirty-five, physician, admitted to Mount Sinai Hospital (Surgical service of Dr. Neuhoof and Otolaryngological Service of Dr. Yankauer), on Nov. 5, 1930.

Previous History.—Negative.

Present Illness.—Three days previous to admission (Nov. 2, 1930) patient had been admitted to Willard Parker Hospital, with a suspected laryngeal diphtheria following an attack of respiratory difficulty accompanied by stridor and pain in the chest. Had also complained of dysphagia and hoarseness, and an acute pharyngitis and laryngitis, and a membranous pharyngeal ulceration extending to the larynx were found. Temperature was

102° F., and later 104° F. The throat culture showed *Streptococcus hemolyticus*. The blood picture was apparently normal as the white blood cells were 6,500 with 63 per cent polymorphonuclear neutrophils. Under observation, the patient's condition became worse, with more marked laryngeal involvement. Within a few days the white blood cells diminished to 2,500 without any change in the percentage of polymorphonuclear neutrophils. He received two blood transfusions.

On admission to the Mount Sinai Hospital, the Wassermann reaction was negative. The blood examination showed a profound leucopenia with a marked increase of the non-segmented neutrophils and was as follows:

Hemoglobin	85 per cent
Red blood cells	4,800,000
White blood cells	3,500
Polymorphonuclear nonsegmented cells	65 per cent
Polymorphonuclear segmented cells	10 per cent
Lymphocytes	25 per cent
Degenerative index	88 per cent

Course and Treatment.—The stridor became more marked and the patient experienced a great deal of difficulty in breathing.

A tracheotomy was performed for suspected perilaryngeal phlegmon. The tissue was found to be edematous but no pus was present. Following the operation the temperature gradually returned to normal and the stridor appreciably decreased. Cultures from the region of the laryngeal slough revealed numerous colonies of *Streptococcus hemolyticus*. Sections made from the necrotic tissue removed from the larynx showed necrotic purulent exudate with numerous bacterial colonies. The necrotic lesions in the pharynx healed rapidly. Progress following the tracheotomy was rather slow. The condition of the larynx was considered a necrotizing process as a result of a severe streptococcic infection. The entire right side of the larynx down to the true vocal cords sloughed away. For a time this caused marked discomfort as the loss of structure resulted in aspiration of fluids on swallowing. For a few weeks, nasal feeding was necessary. The patient was also given several transfusions and frequent intravenous glucose infusions. Save for a slight pneumonic infiltration noted only on x-ray examination (Nov. 8, 1930), no complications developed. The temperature became normal about November 10.

After the fourth week in the hospital, the slough in the larynx entirely separated and healthy granulations could be seen. On examination, the distortion and the granulations had a peculiar appearance resembling a neoplastic condition. The patient's voice and general condition improved. When the laryngeal condition was almost healed, about the middle of December, a permanent tracheotomy tube with a safety valve was inserted. Since discharge from the hospital (on Dec. 12, 1930), the patient is apparently well save for the granulomatous condition in the larynx.*

The blood picture (Table II) during the course of the disease is of singular interest. The white blood cells increased to normal by Nov. 13, 1930; however, the nonsegmented cells remained increased during the entire period of observation at the hospital. The degenerative index, which gradually increased the first few days at the hospital, returned to normal about November 24.

DISCUSSION

Three cases of severe infection associated with necrotic lesions of the mucous membranes and an unusual type of leucopenia have been described.

Clinically these cases resembled agranulocytosis. The onset of hypoleucocytic angina was apparently gradual and insidious, about six days elapsing before it fully developed. The first symptom noted was soreness of the throat or tongue, associated with dysphagia. Hoarseness and marked stridor were present

*This patient died on Nov. 17, 1933, after several attacks of true agranulocytosis, which began in May, 1933.

in one case. Fever was usually slight at the onset, but increased as the disease progressed, reaching 104° to 105° F. At the height of the disease, the patients were prostrated, and appeared flushed and toxic. The tongue, tonsils, pharynx, larynx, or all of them showed extensive sloughing. Large, irregular, sharply delineated necrotic areas were present. These were covered with a yellowish or blackish membrane. Throat cultures were positive for hemolytic streptococci. No diphtheria bacilli were found. In one instance, a section of necrotic slough showed a purulent exudate with numerous bacterial colonies. In two cases, the blood cultures were negative; no blood culture was made in the third.

At the height of the disease, the blood picture showed a profound leucopenia with several unique features. Although there was a marked depression in the total white cell count, the differential count retained the usual relations. The presence of a high percentage of nonsegmented polymorphonuclear neutrophils showing degenerative changes in the cytoplasm (Fig. 1) confirmed the impression that a severe infection was present. The hemoglobin, red cell count and platelets were unaffected. In one case the bone marrow was obtained and was found to be hyperplastic with an abundance of mature and immature myeloid cells (Fig. 2). This is in striking contrast to true agranulocytic angina, in which at the height of the disease, there is ordinarily a complete disappearance of the granulocytes from the blood stream, as well as from the bone marrow.

CONCLUSION

A study of the blood picture in the three cases described in this article revealed an unusual form of leucopenia in a condition termed by the authors "hypoleucocytic angina" to describe a clinical syndrome similar to that of agranulocytic angina, but which differs hematologically from the latter as well as from other forms of leucopenia, in that there is a relative polynucleosis of the nonsegmented neutrophils.

THE GRAM PROPERTY OF THE ACID-FAST FORM OF THE TUBERCLE BACILLUS*

OTTO S. KRETSCHMER, A.M., M.D., DENVER, COLO.

IT IS stated in standard textbooks of bacteriology¹ that the tubercle bacillus is gram-positive. It seems that this statement has never been seriously challenged. This property of the tubercle bacillus is of more than mere theoretical interest, it is of definite diagnostic importance due to the claim that certain bodies, called Much "granules," are nonacid-fast gram-positive forms of a hitherto unknown tuberculosis virus which are often alleged to be found instead of the typical acid-fast tubercle bacilli within cold abscesses and in some sputa. The questions raised in this and in a succeeding paper are: (1) Does the tubercle bacillus possess the Gram staining property? (2) Is the Much "granule" stain a modified Gram stain?

DOES THE TUBERCLE BACILLUS POSSESS THE GRAM STAINING PROPERTY?

The purpose of this paper is to demonstrate that the tubercle bacillus in its pathogenic acid-fast phase does not possess the genuine Gram property; that although it is credited with being gram-positive even in the most authoritative treatises,¹ the tubercle bacillus, in its acid-fast stage, is by nature of its physicochemical constitution an organism to which the Gram staining method cannot properly be applied. It is here advisedly stated that, in its pathogenic stage the tubercle bacillus is acid-fast, or, conversely, that the nonacid-fast forms of the organism have not yet been shown to produce typical tuberculosis in the experimental animal. It is true that Much claims by means of his so-called modified Gram stain to have discovered an atypical nonacid-fast gram-positive form of the tuberculosis virus. In a succeeding paper I have taken issue with part of this contention. Sweeny² by means of the single isolation method of Janse-Peterfi in modified form, produced a pathologic condition by the injection of a single nonacid-fast coccoid mutation form of the tubercle bacillus. The disease so produced is not, however, a typical tuberculosis.

When aniline, as employed in the standard Gram stain, is used in combination with a basic stain such as gentian violet or basic fuchsin in staining the acid-fast form of the tubercle bacillus, it renders these dyes acid-fast similar to the action of phenol. This action of aniline is not surprising since it is phenylamine, a benzene ring compound to which class of chemical compounds belongs also phenol. Even before the Ziehl acid-fast method of staining the tubercle bacillus was devised, Ehrlich³ employed a solution of gentian violet in aniline water for demonstrating the tubercle bacillus. He found that this stain resisted decolorization with 33 $\frac{1}{3}$ per cent nitric acid when

*Received for publication, January 7, 1933.

applied to this organism. Hence, instead of the phenol of the carbol-fuchsin, the aniline served with similar efficiency in bringing about retention of the original dye; the aniline dyes were acid-fast similar to the carbol-dyes and likewise alcohol-fast, since Ehrlich's method employed 60 per cent alcohol as decolorizer after application of the acid.

Benians⁴ states that the tubercle bacillus does not require iodine to enable it to withstand alcohol and acid-alcohol decolorizers. He fails to cite experimental work. The same writer says, likewise, that in presence of the acid-fast property it is impossible to fully demonstrate alcohol-fastness, i.e. in the face of acid-fastness, the Gram property cannot be fully exhibited.

EXPERIMENTAL

General Technic.—Untreated tubercle bacilli from a pure culture were applied to slides in a drop of distilled water, and dried in a paraffin oven at 55° C. for a few minutes. No fixation was applied to cause the organisms to adhere so as to prevent the introduction of artefacts.

I. COLD STAINING OF THE TUBERCLE BACILLUS WITH THE GRAM STAIN

Experiment 1.—Tubercle bacilli were stained according to the standard Gram stain but no counterstain was used. The bacilli were stained cold with aniline gentian violet (Stirling's) for one minute, Gram's iodine solution one minute, and decolorized with alcohol until color ceased to come off; no counterstain was applied.

Result: The tubercle bacilli were stained an intense deep purple color.

Experiment 2.—Tubercle bacilli were stained with formalin gentian violet, which is occasionally used in the Gram stain, cold for one minute, Gram's iodine solution one minute, decolorization with alcohol, one slide with and one without counterstain.

Results: Neither slide showed any stained tubercle bacilli.

Experiment 3.—Tubercle bacilli were stained with cold aniline fuchsin, the remainder of the procedure as in (2) above.

Result: The organisms were not stained.

Experiment 4.—Tubercle bacilli were stained with cold crystal violet as carried out by Ruhland,⁵ the remainder of the procedure as in (2) above.

Result: No appreciable staining of bacilli.

Experiment 5.—Purpose: To ascertain the effect of carbol-fuchsin on the tubercle bacillus when applied cold. A preparation of a slide of tubercle bacilli was stained cold with carbol-fuchsin for one minute, not treated with iodine solution nor decolorized with alcohol.

Result: The bacilli were stained faintly or not at all.

Comments on Experiments 1 to 5: Carbol-fuchsin, aniline fuchsin, and crystal violet do not stain the tubercle bacilli when applied cold (for one minute); aniline gentian violet, however, stains the tubercle bacilli intensely when applied cold for one minute, nor does it decolorize with alcohol. Whereas, phenol in combination with fuchsin will stain the tubercle bacilli when applied hot, it fails to stain them when applied cold; aniline, on the other hand, in combination with fuchsin fails to stain the tubercle bacillus when applied cold but when combined with gentian violet does so readily. Formalin gentian violet and crystal violet dyes that are frequently used in Gram staining fail to stain the tubercle bacillus when applied cold.

It will thus be seen that aniline fortifies only gentian violet in cold staining.

II. EFFECT OF IODINE ON THE TUBERCLE BACILLUS

a. *With Alcohol as Decolorizer.*—

Experiment 6.—"Gram" stain without iodine solution. Tubercle bacilli were stained with aniline gentian violet as in Experiment 1 but using no iodine; decolorization with alcohol.

Result: The organisms were stained as intensely as when iodine was used.

Comment on Experiment 6: Iodine is not necessary to "mordant" the aniline gentian violet as is the case with nonacid-fast organisms in order to enable the tubercle bacilli to retain this stain. Hence, one of the essential stages in the classical Gram stain—the "mordanting" with iodine, has thus been shown to be unnecessary when applied to the tubercle bacillus to enable the latter to retain the gentian violet when alcohol is employed as the decolorizing agent.

b. *With Acid-Alcohol as Decolorizer.*—

Experiment 7.—Tubercle bacilli were stained with cold aniline gentian violet for one minute, Gram's iodine solution one minute, acid alcohol (3 per cent HCl in 70 per cent alcohol) until color ceases to come off. This acid alcohol is the same as that employed in the Ziehl-Neelsen stain.

Results: Tubercle bacilli were intensely stained a dark blue color; they were not decolorized by the acid alcohol; in other words, they were acid-fast to the Gram stain.

Experiment 8.—Same as Experiment 7, but without the Gram's iodine solution.

Results: The tubercle bacilli were stained as intensely as in Experiment 6.

Experiment 9.—Living cultures of recently isolated gram-positive pathogenic staphylococci and streptococci were stained according to Gram and decolorized with acid alcohol as employed in the Ziehl-Neelsen stain. They were then counterstained with Bismarck brown.

Results: These gram-positive organisms were completely decolorized by acid alcohol and took the counterstain.

Comment on Experiments 7, 8, and 9: The tubercle bacilli will retain the aniline gentian violet as well when the organisms are not "mordanted" with Gram's iodine solution as when they are so treated, not only after alcohol but also after acid alcohol is applied as decolorizer. This is not the case with pyogenic gram-positive organisms such as staphylococci and streptococci. When these are exposed to acid alcohol even after application of iodine solution they will lose their gentian violet, which is to be expected since they are not acid-fast but only alcohol-fast (gram-positive); the tubercle bacillus, however, is alcohol and acid-fast. This constitutes, consequently, a basic deviation from the Gram stain in the case of the tubercle bacillus, so vital as to force the conclusion that the tubercle bacillus does not possess genuine Gram property since, first, it does not require iodine to remain alcohol-fast, and second, the bacillus stained with aniline gentian violet is acid-fast.

STANDARD GRAM STAIN APPLIED TO CHEMICALLY TREATED TUBERCLE BACILLI

Living tubercle bacilli from cultures were deprived of their acid-fastness by strong acid and alkali. This often is rather difficult to accomplish completely in all of the tubercle bacilli treated, if the morphology of the organisms is to be retained. The purpose of this mode of experimentation was to ascertain the reason for the atypical Gram property of the tubercle bacillus, in

which portion of the tubercle bacillus it is vested, and to determine the Gram property of the tubercle bacillus which has been deprived of its acid-fast property.

Tubercle Bacilli Treated With Sodium Hydroxide.—As Long⁶ has pointed out, the acid-fastness of the tubercle bacillus is highly resistant to this alkali in rather strong solutions. In the following experiments living tubercle bacilli were dried and pulverized by passing through a fine mesh copper sieve (1,936 per sq. in.) and exposed in centrifuge tubes to a 25 per cent solution of sodium hydroxide for varying periods of time. The hydroxide was then carefully decanted so that the bacilli adhered to the wall of the tube, and the organisms washed and centrifuged several times until the washings were neutral to litmus. They were then applied without fixative to slides, placed in the paraffin oven at 55° C. for a few minutes until dry and then stained.

Experiment 10.—Exposure time to 25 per cent sodium hydroxide: five minutes.

Result: Tubercle bacilli well stained with carbofuchsin. The granules seemed somewhat swollen. The intergranular portion of the bacilli generally is not stained with carbofuchsin, it often remains colorless as is frequently the case in untreated bacilli.

Experiment 11.—Exposure time same as Experiment 10. The organisms were Gram stained after application of hydroxide. This shows the granules stained very intensely purple. The intergranular material in many bacilli stains brown with the counterstain (Vesuvín). Hence, we have the apparent anomaly of an organism staining "gram"-positive and "gram"-negative in the same bacillary body.

Experiment 12.—Exposure time: one and one-half hours.

Results: Ziehl-Neelsen stain showed a number of nonacid-fast tubercle bacilli which stained faintly blue with the methylene blue. Those that stained acid-fast were colored a very faint red.

Experiment 13.—Exposure time: one and one-half hours. Gram stain applied.

Results: These tubercle bacilli are stained more intensely with aniline gentian violet than with carbofuchsin in Experiment 10. Some take the counterstain, i.e. they are colored brown by the vesuvín. These tubercle bacilli that have been rendered gram-negative, stain uniformly throughout with no granules whatever, and the bacillary body is intact.

Experiment 14.—Exposure time: four days. Practically all the tubercle bacilli have been disintegrated. However, even after this period of time a rare bacillus staining acid-fast and "gram"-positive is seen.

Experiment 15.—Tubercle bacilli not treated with sodium hydroxide were exposed to Bismarek brown, heating the stain for one minute. No stained tubercle bacilli were to be seen. Some of the extrabacillary amorphous material only stains brown. This effect of Bismarek brown on the tubercle bacillus is in keeping with the work of Hope Sherman.⁷

Comments on Experiments 10 to 15: After being exposed to sodium hydroxide the tubercle bacillus can be made to manifest an apparent anomaly of being simultaneously "gram"-positive and "gram"-negative in the same bacillus. This is explainable by assuming that the sodium hydroxide brings about changes in the intergranular portion of the bacillus facilitating penetration of the Gram counterstain, Bismarek brown, which by itself (Experiment 15), will not adequately stain the untreated tubercle bacillus. This intergranular portion of the untreated tubercle bacillus is often quite resistant to strong dyes as is evidenced by unstained areas between the granules of many of the organisms after the Ziehl-Neelsen stain. This double staining

after treatment with sodium hydroxide can be explained on the basis of Experiments 6, 7, 8, and 9, above. The aniline gentian violet of the Gram stain, as has been shown in these experiments acts as an acid-fast stain for the acid-fast portion, especially the granules of the tubercle bacillus in these treated organisms, and the investment of the nonstaining intergranular portion having been removed or altered by the hydroxide is rendered permeable to the Bismarck brown and shows genuine gram-negative property. As has been seen in Experiment 15, Bismarck brown does not appreciably stain the untreated tubercle bacillus.

Tubercle Bacilli Treated With Sulphuric Acid.—The purpose of this work was to render the tubercle bacillus nonacid-fast with sulphuric acid in a rapid and certain manner and then to study the Gram property of the nonacid-fast organism.

Experiment 16.—Dried living tubercle bacilli that were passed through a fine sieve were exposed to the action of 2.5, 7.5, 10, 15, 20, 50, and 75 per cent sulphuric acid solutions.

Results: The tubercle bacilli in the center of small clumps often remained acid-fast even in the higher percentages, after five minutes' exposure. Hence concentrated sulphuric acid was employed to deprive the organisms of their acid-fastness completely and as quickly as possible without altering their morphology.

Experiment 17.—Concentrated sulphuric acid (sp. gr. 1.84) was applied to pulverized intact tubercle bacilli. The latter floated on the surface and could, after exposure time had elapsed, be skimmed off with a coiled platinum loop and washed with distilled water into a centrifuge tube. The tubercle bacilli were then centrifuged, and repeatedly washed until the wash water was neutral to litmus. The organisms were then applied to slides, dried at room temperature, and stained. When the tubercle bacilli were exposed much longer than five minutes to concentrated sulphuric acid, they generally disintegrated and showed mostly amorphous debris which stained gram-negative. One-minute exposure showed that some of the tubercle bacilli were losing their acid-fast material which latter appeared as round or oval droplets in the optical fields. Often these were still attached to the bacillus which stained blue (nonacid-fast), and the former bright red (acid-fast) (see Plate I).

Results: Thus the acid-fast material was "extracted" by the sulphuric acid from the tubercle bacilli and the bacillus was left morphologically intact, staining gram-negative, if treatment was not too prolonged so as to produce disintegration of the bacillary bodies.

Five minutes' exposure at room temperature brought about a complete abolition of acid-fastness. The bacilli were stained uniformly throughout the bacillary body a bright blue by the contrast stain. With the Gram method of staining the same bacilli stained a brilliant brown with the resubin, the dye being evenly distributed throughout the bacillus and the latter free from all beading. Hence they had been rendered gram-negative by removal of the acid-fast material. The morphology and staining of these tubercle bacilli deprived of their acid-fastness were identical with the staining of nonacid-fast gram-negative young bacilli found in a culture obtained directly from sputum grown on potato medium.

Comment on Experiments 16 and 17: From these experiments it will be seen that after the acid-fast materials in the tubercle bacillus have been removed or destroyed chemically there remains a bacillus "underneath" that is gram-negative. In other words, deprived of its acid-fast material which has no genuine Gram property, the "basic portion" of the tubercle bacillus is gram-negative. This Gram counterstain colors the entire tubercle bacillus uniformly throughout with the Bismarck brown counterstain, both what was the granular and intergranular portion of the organism. These bacilli stained

Fig. 1.—Acid-fast beaded tubercle bacilli which were treated with sulphuric acid, with the results seen in Fig. 2. Note how slender they are in comparison with nonacid-fast forms in Figs. 2 and 3.

Fig. 2.—Ziehl-Neelsen stain of tubercle bacilli after treatment with concentrated sulphuric acid for one minute. Bacilli have taken the counterstain: they are nonacid-fast. Acid-fast bacilli are still clinging to a tubercle bacillus, are shown. These latter bacilli were gram-negative. The beading has disappeared. Tubercle bacilli stain uniformly and their morphology is intact. They resemble the nonacid-fast bacilli seen in Fig. 3.

Fig. 3.—Culture stained with Ziehl-Neelsen stain, showing acid-fast, some nonacid-fast and partially nonacid-fast forms. Note similarity of the morphology of the "young" nonacid-fast bacilli to those deprived of their acid-fastness by sulphuric acid shown in Fig. 2.

Fig. 4.—Gram stain (Bismarck brown counterstain) of a culture of tubercle bacilli containing some nonacid-fast tubercle bacilli shown in Fig. 2. The bacilli are heavy rods and stain evenly without beading.

after treatment with sodium hydroxide can be explained on the basis of Experiments 6, 7, 8, and 9, above. The aniline gentian violet of the Gram stain, as has been shown in these experiments acts as an acid-fast stain for the acid-fast portion, especially the granules of the tubercle bacillus in these treated organisms, and the investment of the nonstaining intergranular portion having been removed or altered by the hydroxide is rendered permeable to the Bismarck brown and shows genuine gram-negative property. As has been seen in Experiment 15, Bismarck brown does not appreciably stain the untreated tubercle bacillus.

Tubercle Bacilli Treated With Sulphuric Acid.—The purpose of this work was to render the tubercle bacillus nonacid-fast with sulphuric acid in a rapid and certain manner and then to study the Gram property of the nonacid-fast organism.

Experiment 16.—Dried living tubercle bacilli that were passed through a fine sieve were exposed to the action of 2.5, 7.5, 10, 15, 20, 50, and 75 per cent sulphuric acid solutions.

Results: The tubercle bacilli in the center of small clumps often remained acid-fast even in the higher percentages, after five minutes' exposure. Hence concentrated sulphuric acid was employed to deprive the organisms of their acid-fastness completely and as quickly as possible without altering their morphology.

Experiment 17.—Concentrated sulphuric acid (sp. gr. 1.84) was applied to pulverized intact tubercle bacilli. The latter floated on the surface and could, after exposure time had elapsed, be skimmed off with a coiled platinum loop and washed with distilled water into a centrifuge tube. The tubercle bacilli were then centrifuged, and repeatedly washed until the wash water was neutral to litmus. The organisms were then applied to slides, dried at room temperature, and stained. When the tubercle bacilli were exposed much longer than five minutes to concentrated sulphuric acid, they generally disintegrated and showed mostly amorphous debris which stained gram-negative. One-minute exposure showed that some of the tubercle bacilli were losing their acid-fast material which latter appeared as round or oval droplets in the optical fields. Often these were still attached to the bacillus which stained blue (nonacid-fast), and the former bright red (acid-fast) (see Plate I).

Results: Thus the acid-fast material was "extracted" by the sulphuric acid from the tubercle bacilli and the bacillus was left morphologically intact, staining gram-negative, if treatment was not too prolonged so as to produce disintegration of the bacillary bodies.

Five minutes' exposure at room temperature brought about a complete abolition of acid-fastness. The bacilli were stained uniformly throughout the bacillary body a bright blue by the contrast stain. With the Gram method of staining the same bacilli stained a brilliant brown with the resurin, the dye being evenly distributed throughout the bacillus and the latter free from all beading. Hence they had been rendered gram-negative by removal of the acid-fast material. The morphology and staining of these tubercle bacilli deprived of their acid-fastness were identical with the staining of nonacid-fast gram-negative young bacilli found in a culture obtained directly from sputum grown on potato medium.

Comment on Experiments 16 and 17: From these experiments it will be seen that after the acid-fast materials in the tubercle bacillus have been removed or destroyed chemically there remains a bacillus "underneath" that is gram-negative. In other words, deprived of its acid-fast material which has no genuine Gram property, the "basic portion" of the tubercle bacillus is gram-negative. This Gram counterstain colors the entire tubercle bacillus uniformly throughout with the Bismarck brown counterstain, both what was the granular and intergranular portion of the organism. These bacilli stained

Fig. 1.—Acid-fast beaded tubercle bacilli which were treated with sulphuric acid, with the results seen in Fig. 2. Note how slender they are in comparison with nonacid-fast forms in Figs. 2 and 3.

Fig. 2.—Ziehl-Neelsen stain of tubercle bacilli after treatment with concentrated sulphuric acid for one minute. Bacilli have taken the counterstain; they are nonacid-fast. Acid-fast droplets, one of which is still clinging to a tubercle bacillus, are shown. These latter stained "gram-positive," whereas the bacilli were gram-negative. The beading has disappeared and the nonacid-fast tubercle bacilli stain uniformly and their morphology is intact. They resemble the nonacid-fast bacilli seen in Fig. 3.

Fig. 3.—Culture stained with Ziehl-Neelsen stain, showing acid-fast, some nonacid-fast and partially nonacid-fast forms. Note similarity of the morphology of the "young" nonacid-fast bacilli to those deprived of their acid-fastness by sulphuric acid shown in Fig. 2.

Fig. 4.—Gram stain (Bismarck brown counterstain) of a culture of tubercle bacilli containing some nonacid-fast tubercle bacilli shown in Fig. 2. The bacilli are heavy rods and stain evenly without beading.

with the counterstain possess none of the aberrant morphology of the untreated acid-fast tubercle bacilli, but are uniform rods of varying lengths, with rounded ends. Moreover, the tubercle bacillus may be violently deprived of its acid-fastness and of its so-called gram-positivity and yet retain its morphology, that is, not to be disintegrated. Benians⁴ found that mechanical disruption of the body of the tubercle bacillus destroyed both its acid-fastness and its "gram-positivity" and rendered the bacillary débris gram-negative. However, it will be seen from the above work that the tubercle bacillus may be deprived of its acid-fast property completely without causing disintegration of the bacillary body. The capsule of the bacillus, if it has one, following treatment with sulphuric acid seems to remain intact as the bacillus retains a definite bacillary morphology after such exposure. The bacillus so deprived of its acid-fast material appears wider than the average tubercle bacillus, has rounded ends, and stains uniformly throughout without granulations or unstained areas. The impression one receives is that the tubercle bacillus consists primarily of a gram-negative bacillus (young organism) of rather uniform staining property which in the course of its metabolism becomes encrusted externally to its investment ("capsule") or within the latter with acid-fast, lipoidal material which is frequently unevenly distributed in the form of granules. Simultaneously with this process the "capsule" becomes impervious to all dyes as is evidenced by the unstained portions of the bacillus between the granules. The presumption is that the hydroxide dissolves off this investment.

STAINING OF THE ETHER EXTRACT OF THE TUBERCLE BACILLUS

Experiment 18.—Tubercle bacilli were extracted with ether for ten months. This ether extract was placed on slides and the ether allowed to evaporate. The slides were then stained according to Ziehl-Neelsen and Gram methods.

Result: The former showed only slightly acid-fast staining property; the latter stained a deep purple.

Comment: It would appear that the lipoidal extract of the tubercle bacillus is more "gram"-positive than acid-fast, due probably to the greater resistance of aniline gentian violet than carbolfuchsin to acid alcohol and also to the greater visibility of the former. The ether extract is, like the unextracted lipoid in the tubercle bacillus, both alcohol- and acid-fast and hence has no genuine gram-positive property since the latter demands only a resistance to alcohol (alcohol-fastness).

DISCUSSION

In order to clarify the discussion it might be well to define what is meant by the Gram and by the acid-fast property. For an organism to possess the Gram property it must either lose or retain the original stain which has been "mordanted" with the special Gram's iodine solution, when alcohol or acetone are applied as decolorizers. In the former case the organism is "gram-negative," in the latter "gram-positive." An organism is acid-fast if the dye with which it has been stained fails to be removed when treated with dilute mineral acids. Incorporated with this acid-fast staining solution is some chemical

such as phenol to aid penetration. In addition it may be necessary to apply heat to bring about penetration into the microorganism. Alcohol is not an essential decolorizing ingredient in the acid-fast staining method, it being employed on the assumption that the tubercle bacillus is more resistant to it than are certain other acid-fast organisms such as the *B. lepra* and the smegma. Stitt,⁸ however, states that he has found smegma bacilli often to be quite resistant to alcohol.

In Experiment 6 it was found that the tubercle bacillus requires no iodine to enable it to retain the original Gram stain in the face of alcohol decolorization. In Experiment 8 it was seen that the tubercle bacillus retains the Gram dye (aniline gentian violet) not only when alcohol, but also when acid alcohol is applied. Hence, it must be concluded that the tubercle bacillus does not possess the typical Gram property, in fact the Gram dye (aniline gentian violet) actually proves to be acid-fast for this organism, since it is not decolorized by 3 per cent HCl in 70 per cent alcohol. The other dyes sometimes employed for Gram staining such as crystal violet and formalin gentian violet do not even adequately stain the organism. As seen in Experiments 1 and 2 the only one of these Gram dyes that will penetrate the tubercle bacillus when applied cold is aniline gentian violet. Not even carbolfuchsin will do so. In short, the acid-fast property of the tubercle bacillus precludes the possibility of its possessing the real Gram property.

From these staining experiments one is led to believe that both the acid-fast property and the "gram-positivity" of the tubercle bacillus are attributable to the same substance or substances in this organism. In order to ascertain this, tubercle bacilli were exposed (Experiments 10 to 17) to a 25 per cent solution of sodium hydroxide and to concentrated sulphuric acid with the following results: (1) Complete removal of the acid-fast property and at the same time of the "gram-positivity." This would seem to indicate that both properties depend upon the same substance or substances. This appears to be confirmed further by Experiment 18 in which the ether extract retains both the carbolfuchsin and the aniline gentian violet of the Gram staining method. (2) When tubercle bacilli are exposed for a very short time to strong acid or alkali, they may still remain acid-fast, but when stained according to Gram, part of the individual bacillus may stain "gram-positive" in the granular portion of the organism, and part of the bacillus stains gram-negative in the areas between the granules. This merely confirms the previous finding, under (1), of the identity of the acid-fast and of the "gram-positive" material. A change in the "capsule" in the intergranular area seems to have been produced by acid and by alkali, permitting the passage of the Gram counterstain where ordinarily the Bismarck brown does not penetrate, it being the most resistant portion of the tubercle bacillus to stain. The granules on the other hand are the acid-fast areas of the organism. (3) When tubercle bacilli were treated with concentrated sulphuric acid for a short time, droplets appeared outside of the organisms which retained both the carbolfuchsin and the aniline gentian violet in the face of acid-alcohol decolorization, they were acid-fast, still more confirming the opinion that both acid-

fast and "Gram" properties depend upon the same substance when applied to the tubercle bacillus. (4) Tubercle bacilli deprived of their acid-fast material by means of alkali or acid, stain gram-negative in the true sense, that is, they are decolorized by alcohol after previous application of Gram's iodine solution.

In studying the morphology of tubercle bacilli that have been deprived of their acid-fastness a striking resemblance was observed between them and young nonacid-fast tubercle bacilli in that: (a) their morphology is that of uniform rods with rounded ends and of varying lengths, but of remarkably uniform diameter, which latter is much greater than that of the average tubercle bacillus (see Plate I); (b) uniform distribution of stain throughout the bacillary body, with entire absence of beading. The bacilli are less bizarre than is the acid-fast form of organism. One is consequently led to conclude that when the tubercle bacillus is stripped of its unusual property that sets it apart from most other pathogenic organisms, namely, its acid-fastness, it is gram-negative. When the young nonacid-fast tubercle bacillus assumes acid-fastness, one may picture it as becoming impregnated, or perhaps encrusted with a waxy lipoidal covering which does not always distribute itself uniformly but often in beaded fashion and is bound to the capsule in a physico-chemical union. From the manner in which the acid-fast material is removed by sulphuric acid and by sodium hydroxide, as seen in this work, leaving a morphologically intact bacillus underneath, it would seem likely that this material merely forms an investment over or within the capsule, but not within the bacillary protoplasm, otherwise one would expect a disturbance in the morphology of the bacillus consequent upon its removal.

CONCLUSIONS

1. The only Gram dye that adequately stains the tubercle bacillus when applied cold is aniline gentian violet. This dye has greater penetrability than the classical carbolfuchsin of the acid-fast technic which has to be applied hot.

2. It has been found in the above work that when aniline gentian violet used in the classical Gram stain has been applied, the tubercle bacillus will retain this dye not only after application of alcohol but also after decolorization with acid alcohol (3 per cent HCl). Consequently this Gram dye proves to be acid-fast for the tubercle bacillus.

Thus it will be seen that the acid-fast form of the tubercle bacillus *possesses no true gram-positive property* because the acid-fast property renders this impossible since none of the other Gram dyes penetrates the organism under like circumstances (applied cold).

3. When the tubercle bacillus is completely deprived of its acid-fast property either by strong acid or alkali, it becomes gram-negative, similar to young cultures which likewise often contain nonacid-fast tubercle bacilli that stain gram-negative. On the other hand, so long as the tubercle bacillus retains the "Gram" stain, it will also invariably be found to be acid-fast, if not with carbolfuchsin, at least with carbol or aniline gentian violet.

4. When the tubercle bacillus is deprived by acid or alkali of its acid-fast property, it loses its beading and stains uniformly, becomes gram-negative, and resembles the young nonacid-fast form of the organism.

5. The suggestion is herewith offered that in the future, writers of books and articles on tuberculosis when describing the staining properties of the tubercle bacillus state that in its acid-fast pathogenic form it does not possess true Gram property; that the Gram technic, as a differential stain, cannot be applied to this organism because of the presence within it of the acid-fast material.

Acknowledgment: The tubercle bacilli for this work were obtained from Dr. M. Chernyk of the Clinical Department, National Jewish Hospital for Consumptives of Denver, the Parke-Davis Co., and from Dr. S. A. Petroff I obtained a culture of strain II 37, to whom thanks are here extended.

VARIATIONS OF THE SOLUBILITY OF THE CERVICAL MUCUS IN RELATION TO THE MENSTRUAL CYCLE*

G. L. MOENCH, M.D., NEW YORK, N. Y.

IN A VERY painstaking series of experiments Kurzrok¹ has investigated the lytic action of semen on cervical mucus. He found that normal semen digests normal cervical mucus and suggests that either changes in the lytic action of the semen or in the character of the cervical mucus or both may produce sterility. Mucopurulent cervical secretion for instance Kurzrok has always found to be nondigestible by semen.

In the course of examining sterile couples I have repeated some of Kurzrok's experiments using mainly the gross method of immersing the cervical mucus in the semen. I consider this gross method less subject to misinterpretation than the microscopic penetration method as far as the solution or digestion of the cervical mucus is concerned.

The results of my experiments were not quite as expected and appeared at first to be rather fortuitous. Thus using a normal semen from a clinically fertile man on four different, apparently normal, mucus shreds from the cer-

*Received for publication, February 14, 1933.

vices of four women I found varying degrees of solubility. At the same time the microscopic penetration method showed, to my eyes at least, no significant variations as far as the penetration of the cervical mucus by the spermatozoa was concerned. Again in four sterile couples where I used the husband's semen with the apparently normal cervical mucus of the wife and also on three of these the semen of the known fertile man my results were inconclusive since the semen from the normal man did not produce much dissolution of the cervical mucus from two of the four women who were apparently normal. However in three cases where the two semen specimens had been used similar results were obtained with both semen samples.

As far as infected mucus was concerned I obtained practically no digestion of it with semen by the gross method but did see penetration of the spermatozoa into the mucopus. The degree of penetration seemed to depend solely on the viscosity of the mucopus which thus constituted a mechanical barrier to the progress of the sperms. With rather fluid pus penetration of the sperms was evident and I have shown before² that pus itself does not inhibit the spermatozoa. That the gross digestion of the cervical mucus by the semen did not at times agree with the penetrability of the same cervical mucus by the sperms may easily be explained by assuming that the fibrin and pus in the specimen may form a network or a sort of skeleton enmeshing the mucus itself. So even if the mucus itself were dissolved no gross changes would be prominent in the original specimen from the cervix. This theory was verified to some extent by the microscopic appearance of the mucus shred after it had been subjected to the influence of the semen for some time. At any rate there was less free mucus in the cervical mucus specimen of this type after immersion in the semen for a while than there had been before.

The assumption of the penetrability of the cervical mucus by the spermatozoa varying directly as its viscosity agrees very well with clinical experiences since markedly infected cervices in which the canal itself is not plugged by the tenacious mucopus frequently allow of pregnancy whereas those cervices which are plugged up solidly by a thick mucopurulent shred prevent pregnancy just as long as the condition remains unrelieved, other conditions of course being normal.

Thus the penetration of the cervical mucus seemed to me to hinge more on the viscosity of the mucus or mucopus itself than upon the lytic action of the semen. At the same time no one will deny that, just as the number, the motility, the morphology, and the biometrics of the sperms may vary so also may the lytic action of the semen be variable. Thus while far from denying any of the interpretations Kurczok made in his experiments I could not from my own few cases (11 at that time) see any correlation between the solubility of the cervical mucus in the semen and fertility except so far as the viscosity of the cervical mucus when marked prevented the ascension of the sperms but this was then a purely mechanical and not a chemical process.

Some time after these experiments were made I had occasion to try out again the solubility of the cervical mucus in semen in investigating another sterile couple. I found that the cervical mucus which was apparently normal

was only slightly soluble in the semen of the husband. As a control I used the same cervical mucus with the semen of a known clinically fertile man and again obtained the same result. As a second control I tested out the same two semens on the cervical mucus of the perfectly normal wife of the fertile man and obtained a fairly marked digestion of the mucus by both semen specimens. These results now could mean only one of three things, either my technic was wrong, or there existed selective fertility inasmuch as a particular normal semen would not dissolve one normal specimen of cervical mucus whereas it would attack another such normal specimen, or there were undetected factors acting on the cervical mucus or the semen which would influence the reactions obtained.

As far as my technic was concerned I could discover no flaws in it but rechecked the findings the next day by means of the microscopic penetration method. However, this method did not offer any solution of the problem. My gross method was the same as that used by Kurzrok except that I used undiluted semen since dilution not only diluted the semen but also changed the osmotic pressure, the buffer reaction of the semen, etc. However, using the semen undiluted should if anything have made my results more accurate instead of confusing.

As far as selective fertility is concerned I have discussed this question in previous papers.³ Since all the known human races do produce fertile offspring by interbreeding, it seems illogical to assume that nature would deliberately limit procreation to certain chance combinations of a special class such as a particular type of semen combined with a particular type of cervical mucus. A similar attempt to explain some cases of apparently selective fertility has also been made in connection with the various blood groups but investigations have showed no foundation for this theory. The explanation of selective fertility is usually very much simpler (see Moench, l.c.).

There remained then only the third possibility, that of some undetected change in either the semen or the cervical mucus.

Two weeks later I was able to recheck my findings on the same patients and obtained the unexpected result that the cervical mucus of the childless woman was now more soluble in the two semen samples than before and more soluble than the mucus from the cervix of the fertile woman. This latter sample of mucus indeed was very little affected by the semen. A repetition of the tests the next day again gave the same results but a different specimen of mucus showed some solubility in the semen. This could only mean that the cervical mucus in both of these women had undergone some change. On checking up the history of the patients it was found that in the first experiment the sterile woman had been in the premenstrual period and the fertile one in the first half of the menstrual cycle whereas two weeks later the conditions were of course reversed.

In view of these results I next tried out cervical mucus from two pregnant women in the seventh and ninth month of pregnancy respectively with the semen of the same fertile man and also with the semen of another normally fertile man but obtained no dissolution of the cervical mucus whatsoever. The cervical mucus from two cases of amenorrhea was also tested but the

results were inconclusive. One specimen of mucus showed some digestion, the other none at all. However, we were not in the position to determine the amount of female sex hormone in the blood of the two patients and without this determination can draw no conclusions.

Unless then we assume that the lytic action of the semen varies without any apparent cause we must draw the conclusion that the solubility of the cervical mucus varies with different times of the menstrual cycle. This is not a difficult thing to believe. Even clinically the cervical mucus in the same woman seems at times to be more fluid than at other times. It is known that follicular fluid and also the normal secretion of the fallopian tubes and the uterine body⁴ dissolve the cervical mucus. In fact the rubbery consistency of the cervical plug during pregnancy has been explained as being due to the absence of the solvent action of the combined tubouterine secretions. That these secretions, especially the uterine one, are dependent more or less on ovarian activity is well known. Thus the concept of the varying properties of the cervical mucus is nothing new. Perhaps we have in addition a direct action of the ovary through the folliculin in the blood stream on the cervical mucus.

The few cases presented thus seem to point to a variation in the properties of the cervical mucus dependent apparently on ovarian activity. At the same time proper specimens are hard to obtain, the work requires much time, and there are so many pitfalls that one must hesitate to make more than tentative assumptions. I present these few cases only because they may point the way for further investigations and may prevent too hasty and incautious interpretations of the findings obtained by this method of investigation of sterile couples.

30 EAST 58 STREET.

A CLINICAL STUDY OF BLOOD IRON AND HEMOGLOBIN*

C. W. DOWDEN, M.D., AND CLYDE MCNEILL, M.D., LOUISVILLE, Ky.

WITH THE TECHNICAL ASSISTANCE OF J. D. MCNEILL, B.S.

WE ARE approaching this subject with a healthy skepticism, born of the belief that, in spite of the great progress that has been made in hematology during the past few years, we are still surrounded by a mass of doubtful and uncertain data that leaves us far from a simple and satisfactory working basis. One must respect and accept as authoritative the original work of Haden,¹ Osgood and Haskins² and others for their valuable contributions. We cannot but feel that our immediate clinical need is the adoption of simpler methods to remove us from much of the chaos that for the past few years has served to confuse us. We believe that for many years at least the estimation of the number of red blood cells and the hemoglobin per given quantity of blood, as well as their relationship to each other, will constitute the chief desideratum in hematologic studies. One must also give greater thought to the question of iron in its relationship to hemoglobin.

It seems unnecessary to further stress the great importance of reporting the amount of hemoglobin in grams per 100 c.c. of blood, but a citation of a few of the existing errors will not be amiss. For instance one of the Sahli instruments is so graduated to indicate 100 per cent hemoglobin as containing 17.2 gm., one of the Dare instruments to contain 13.8 gm. of hemoglobin, representing a difference of more than 20 per cent, perhaps better shown by the equation, viz.:

$$17.2 \text{ gm. Sahli} = 100 \text{ per cent}$$

$$17.2 \text{ gm. Dare} = 124 \text{ per cent}$$

It should be known also that there is a wide difference in various Sahli instruments as well as in the Dare instruments. Certainly percentage reports are meaningless and even when accompanied by the name of the method used are not accurate unless such instrument has been standardized with one of the more accurate methods to be mentioned. What should be accepted as a normal average figure for the number of grams of hemoglobin contained in 100 c.c. of blood, and what should be accepted as a normal average figure for the number of red blood cells per cubic millimeter of blood? Personally, we believe that no single figure will serve the purpose with even a fair degree of accuracy. Such figures are ordinarily obtained by taking an average for a large number of so-called normals. In this number we will find a range of from 11.0 to 16.5 (a difference of 34 per cent) gm. of hemoglobin per 100 c.c. of blood, and a range of from 4,000,000 to 6,000,000 (a difference of 34 per cent) for the number of red blood cells per cubic millimeter of blood. Certainly such varia-

*Received for publication, December 29, 1932.

tions are too great to permit of accurate averaging. The question naturally arises as to what is normal blood. An individual may be subjectively healthy and with perfectly normal functional tests of all kinds and still have comparatively low hemoglobin and red cell counts. Such findings are not uncommon among nurses, technicians, secretaries, etc., and such individuals constitute a large percentage of our so-called normal series. Conversely an individual may have advanced heart, kidney, lung, gastrointestinal, or other pathologic conditions with blood examinations much nearer the generally accepted average than the class previously mentioned (Table IV). These individuals are not used in the normal series.

Both the quantity of hemoglobin and the number of red blood cells are variables, depending probably upon age, sex, climate, food, exercise, and barometric pressure. One of us (J. D. McN.) examined the blood of one patient daily for a month and hourly for a day and found the red blood count to vary from 5,128,000 to 6,176,000 and the hemoglobin from 11.3 gm. to 15.3 gm. With such variations why not abolish such terms as "normal averages" and substitute "a normal range" for hemoglobin and red blood cells as we do for the chlorides, sugar, cholesterol, and the nitrogenous products of the blood.

This study includes about one hundred examinations of the blood made upon 81 individuals (Table I). We are unable to explain the difference between the average number of red cells in the normal bloods of our series and the normal bloods reported by others. The fact remains, however, that a count of five million is a rare exception rather than the rule, with a large percentage running from four to four and a half million. Each of these counts, as well as

hemoglobin determinations, have been made independently by two different workers in different laboratories, using standardized equipment, and discarding results when the two counts did not come within the average limits of error. Furthermore, the work was done by skilled hematologists and not by the usual laboratory technicians. The experience of other reliable laboratories convinces us that in Kentucky at least a normal red cell count of five million is the ex-

Chart 1.—Comparing hemoglobin from iron (Kennedy) with Osgood and Haskin's method.

ception and the average is from 4.3 to 4.5 million, depending largely upon the source of the normals.

Greater accuracy attends the proper determination of the hemoglobin when the method used has been carefully checked with the accurate oxygen capacity method of Van Slyke,³ or the iron method of Kennedy or Wong. Inaccuracy of various methods has been stressed by Osgood and Haskins,² Karshan and Freeman,⁴ Haden,¹ Lindsay Rice and Sellinger,⁵ Robscheit,⁶ and

others. The chief objection to the acid hematin methods seemed to lie in the time required for development of the color, fading of standards, variation in standard discs, and difficulty in reading small quantities of hemoglobin. The Osgood and Haskins is probably the most accurate of the acid hematin methods provided the standard solution is properly prepared and the proper corrections made for variations in temperature. The Palmer⁷ method is quite accurate if the standard is frequently checked. The photoelectrometer of Sanford and Sheard⁸ and the spectrophotometer of Haden⁹ are apparently accurate methods, checking closely with the oxygen capacity method or the iron method. Although quantitative determinations of iron in the blood were made as early as 1820¹⁰ and at long intervals following that, the most recent by Berman in 1918,¹¹ Brown in 1922,¹² Wong in 1928,¹⁴ and Kennedy in 1927,¹⁵ the method received little attention until its clinical application by Powers and Murphy.¹⁶

Of the methods of Wong¹⁴ and Kennedy¹⁵ the latter points out that Wong, like others, has overlooked the question of dissociation and continued to work with aqueous solutions. The results, however, by the two methods check so very closely that the criticism may well be ignored.

Using Kennedy's¹⁵ method Powers and Murphy¹⁶ found the amount of iron in the blood to be within singularly narrow and standard limits for normal adults. They consider it the most accurate criterion yet devised for evaluating the true status of patients with secondary anemia. In a later article Murphy, Lynch and Howard¹⁷ reported a large number of blood iron determinations in normal individuals, and also in the primary and secondary anemias, as well as a variety of other conditions. For normal young men they found an average of 44.84 and for young women an average of 42.84 mg. per 100 c.c. of blood. Using the same method, we find very close agreement with an average of 44 for all normal cases. As would be expected, the results parallel closely the hemoglobin curve in all cases. They also suggested the term "iron index" (obtained by dividing the mg. of iron in 100 c.c. of blood, by the number of red blood cells in millions per 1 c.mm. of blood) to represent the amount of iron in the individual red cell. They found for this an average of 8.4 (strictly speaking $8.4 \text{ mg.} \times 10^{-11}$) for normals, and following in a general way the color index curve. Since our red blood counts are lower on an average, the average normal index is higher, being as consistently 10 in our series as the 8.4 of their series (Tables I and IV).

Both Kennedy¹⁵ and Wong¹⁴ have used the iron content of the blood for accurately determining the amount of hemoglobin. When it is possible to obtain results for the iron content of tissue or fluids, that are accurate to the third decimal and with the molecular weight of the hemoglobin molecule known (though the structure may be in doubt), it becomes immediately apparent that the quantity of iron expressed in milligrams divided by the iron portion of the hemoglobin molecule 0.334 by Wong and 0.334 by Kennedy) can scarcely be exceeded for accuracy when properly decimated to represent the quantity of hemoglobin in gm. per 100 c.c. of blood. The work of Riecker,¹⁸ however, seems to prove that in normal individuals there is an average of 1.1 mg. (± 0.022) of

iron in the blood serum, and this quantity is increased in pernicious anemia particularly and slightly decreased in certain other conditions. In our study we have assumed (possibly wrongly) that cognizance of this nonhemoglobin iron

has been ignored in the methods of Kennedy and Wong, and we have, therefore, subtracted 1 mg. from the total iron content of the blood and then multiplied the result by 0.3 (equal to dividing by $0.333\frac{1}{3}$, instead of the 0.334 and 0.335 used by Kennedy and Wong respectively). While this method makes a difference of less than 2 per cent it has been used with the belief that accuracy was increased to this extent. The oxygen capacity method of Van Slyke² compares so very closely with both the Wong¹⁴ and Kennedy¹⁵ methods that little or no doubt should be entertained as to the accuracy of any of the three methods. Contrary to the general belief we consider both iron methods quite simple and easily completed in about fifteen minutes. We prefer, however, the

Kennedy method¹⁵ because it allows time for other work while the iron mixture is being digested, and, furthermore, the colorimetric readings are definitely sharper. Any of the three methods may be safely used for standardizing hemoglobinometers and checking the accuracy of other methods.

In our experience, as well as in the experience of others, the Osgood and Haskins² acid hematin method gives results closely paralleling the results of

Chart 2.—Showing variation in grams of hemoglobin per 100 c.c. of blood for 100 per cent readings. May also be used for quickly converting percentage into grams.

any of the three standard methods. We believe, therefore, that a determination of the iron content of the blood, the iron content of the individual cell, and the determination of the hemoglobin by the iron method are all most valuable additions to our knowledge of hematology. They assume no averages and deal directly with the number of red blood cells and the hemoglobin found in the individual specimen. Of similar importance is the determination of the amount of hemoglobin in the individual cell. This is done by dividing the hemoglobin in grams per 100 c.c. of blood by the red cells in millions per c.mm.

of blood. The result is expressed in grams times 10^{-12} , or in billionths of a milligram per red cell, according to the following formula:

$$\frac{\text{Hb. in gm.} \times 10}{\text{red cells in millions}}$$

Example: R. B. C. 3,500,000, Hb. 10.5 gm.

$$\frac{10.5 \times 10}{3.5} = \frac{105}{3.5} = 30 \text{ billionths of a mg. per R. B. C. or } 30 \times 10^{-9} \text{ mg.}$$

The color index, determined in our series by the method of Cullen,¹⁹ cannot be quite so accurate, since it assumes five million red cells to be normal,

TABLE V

A ROUTINE REPORT OF A BLOOD EXAMINATION (MARTIN & MCNEILL LABORATORIES)

BLOOD EXAMINATION

R.B.C.	2,896,000-2,970,000 (repeated)
Hemoglobin (Osgood & Haskins)	9.0 gm. per 100 c.c. blood (normal about 15)*
Average amount per red cell	31 billionths of a mg. (normal about 30)*
Blood iron	30 mg. per 100 c.c. blood (normal about 45)
Iron index	10.3
W.B.C.	20,050-21,050 (repeated)

DIFFERENTIAL

	<i>Romanowsky Stain</i>	<i>Supravital Stain</i>

Lymphocytes	2.0	7.0	1,400
Immature lymphocytes	0.0	1.0	200
Smudges	39.0	0.0	0
	100.0	100.0	20,000

Platelet count	25,000
Arneth's index	89 (normal about 60)
Reticulocytes	10%
Malarial parasites	None

The number of red cells is considerably reduced, but the average amount of hemoglobin per red cell is normal, due to an increase in the average size of the cells. Many of the large cells are polychromatic, and a number of normoblasts and megaloblasts are present. There is very little distortion.

Thirty-nine per cent of the white cells are so fragile as to be destroyed in pulling a smear. These fragile cells are identified in the supravital preparation as myeloblasts. These cells have a large round nucleus with several nucleoli and a basophilic cytoplasm. All gradations between these nongranular cells and the typical adult neutrophile can be found.

Impression: Myeloblastic leucemia.

*The percentage of hemoglobin of this patient varies according to the normal standard of hemoglobin selected—for instance, with the Sahli standard it is 52% (color index 0.9), and with the Dare standard it is 66% (color index 1.2).

and this factor enters into the equation. The results, however, conform closely with our general knowledge of what this should be, namely, high in pernicious anemia and low in secondary anemia.

It is our belief that a properly reported blood examination should contain the following data: (1) sufficient counts of the red blood cells and the white blood cells until they check within the accepted limits of error. (2) Hemoglobin determinations by the iron method of Wong¹¹ or Kennedy,¹² or the acid hematin method of Osgood and Haskins,² (3) the average amount of hemoglobin per red cell, (4) the blood iron in milligrams per 100 c.c. of blood, and (5) the iron index, (6) a supravital stain of the white cells as well as examination of the stained smear (this we believe should never be omitted and furnishes information not obtainable from the stained smear), (7) a platelet count, (8) reticulocyte count, and (9) interpretation of the findings and explanation of various hemoglobin standards (Table V). Thus it will be seen that a complete hematologic study is far from the simple procedure that has been used for years and impossible of accomplishment in the ten minutes that has been allotted and boasted for it. Most technical procedures in the laboratory have been greatly simplified without affecting their accuracy, but with our increasing knowledge of the blood, the procedure, if accurate, is becoming more difficult and more time-consuming, which is regrettable from many standpoints, the least of which is by no means financial. Because of the time consumed and the skill required it should not be included along with a urinalysis in a so-called routine examination, but accredited the same dignity that is accorded other special procedures.

321 WEST BROADWAY

BLOOD STUDIES IN HYPERTHYROIDISM*

R. GOTTLIEB, M.Sc., M.D., MONTREAL, CANADA

GENERAL attention was first drawn to the importance of the blood picture in hyperthyroidism by the exhaustive studies of T. Kocher¹ and his co-workers. References to the blood changes occurring in hyperthyroidism were, however, made before Kocher's studies by Ciuffini² and particularly by L. Caro.³ Kocher considered the blood picture as quite typical, namely a leucopenia, neutropenia, and a lymphocytosis. These observations were confirmed by Crotti,⁴ Müller,⁵ Lampe,⁶ Hertz and Lerman,⁷ and others. Some observers, however, could not quite confirm the so-called "Kocher blood picture," e.g., Plumer in his extensive study of 578 cases. The leucopenia particularly has not been found regularly. If one considers, however, the fact that patients suffering from hyperthyroidism are frequently subject to profuse perspiration and diarrhea, which consequently leads to a certain degree of dehydration and blood concentration, one can easily understand the occasional absence of the leucopenia; in other words the blood concentration may mask the presence of the leucopenia.

The following morphologic blood studies were undertaken originally upon the request of Professor E. W. Archibald, who had made, about ten years ago, the observation, in several cases, that the blood from the thyroid vein contained a much higher percentage of lymphocytes than the blood from the thyroid artery, or the peripheral capillary blood. The difference at that time was calculated in percentages, and it was found in two cases that a percentage of between 30 and 40 in the thyroid artery, and in the peripheral capillary blood was in-

*From the Department of Experimental Surgery, McGill University, and the Royal Victoria Hospital.

Received for publication, March 2, 1933.

creased to 75 and even 80 in the blood of the thyroid vein. Samples of blood were taken at the beginning of the operation, immediately upon exposure of the thyroid gland. Professor Archibald desired confirmation of the findings in these few cases. The observation seemed to indicate that a large number of lymphocytes was added to the circulating blood by the fact of its passage through the thyroid gland. With regard to this point the blood of the thyroid artery was compared morphologically with the blood of the thyroid vein in 7 cases; the blood samples were obtained during the operation.

The scope of the investigation was, however, enlarged by me to include an examination of the phagocytic power of the leucocytes, a detailed study of morphologic elements, and also blood examinations upon experimental animals. The phagocytic power of the leucocytes was studied in 6 cases of hyperthyroidism and compared with the normal.

Signs and symptoms of hyperthyroidism were produced experimentally in 3 cats by the injection of thyroxin, and morphologic blood studies made for a period of thirty days and compared with the blood of 3 normal cats.

RESULTS

Erythrocytes and Hemoglobin.—Anemia was not found to be a striking point of the picture, although low normal and slightly subnormal figures are the usual findings. A slight tendency to macrocytosis was usually observed, leading to a color index of 1 or occasionally slightly above (see Table I).

TABLE I
AVERAGE FINDINGS IN 14 CASES OF HYPERTHYROIDISM BEFORE AND AFTER THERAPY

Hb.	82% 11.48 gm.	80% 11.20 gm.
R.B.C.	4,070,000	4,030,000
C.I.	1.02	1.00
W.B.C.	4,660	5,738
Basophiles	13.8 0.3%	5.7 0.1%
Eosinophiles	105.8 2.3%	142.5 2.5%
Myelocytes	0	17.1
Metamyelocytes	0	0.3%
	0	14.25
	0	0.25%
Stab. forms	105.8 2.3%	228 4%
Normal segmented	1,012 22%	1,806.9 31.7%
Hypersegmented	749.8 16.3%	632.7 11.1%
Lymphocytes	2,042.4 44.4%	2,194.5 38.5%
Monocytes	455.4 9.9%	541.5 9.5%
Thromboocytes	213,291	241,333
Remarks	Preoperative	2 weeks postoperative

Total Number of Leucocytes.—The total number of leucocytes was mostly found to be low. Subtotal thyroidectomy usually led to an immediate moderate increase in the leucocyte count, which however returned to the original low level or a slightly higher one within about 2 weeks. The number of leucocytes was found in the differential count to be due to a reduction in granulocytes, especially the neutrophiles.

Basophiles and Eosinophiles.—Although normal in their percentage figures, they show low absolute numbers.

Neutrophiles.—The neutrophilic granulocytes were always found to be diminished, in percentage as well as in their absolute figures. An increased segmentation of the nuclei was a striking feature, leading to a shift to the right (Arneth-Shilling) with slight evidences of degeneration. Immediately after operation and coinciding with the temporary increase in the total number of leucocytes a considerable number of young forms appeared, returning, however, within about two weeks to almost the original formula, irrespective of the clinical condition or basal metabolism rate of the patient.

Lymphocytes.—Lymphocytes always showed a marked, but mostly relative lymphocytosis. There is a very slight relative reduction of the lymphocytosis after operation.

Monocytes.—A high percentage of monocytes was usually present before and after the operation, the presence of a monocytosis was recently pointed out by Hertz and Lerman⁷ (see Table I).

Thrombocytes.—The thrombocytes usually showed low normal or slightly subnormal numbers. After operation there is a temporary increase in the number of thrombocytes, returning, however to the original level in about two weeks.

COMPARISON BETWEEN THYROID ARTERY AND THYROID VEIN

Six of the seven cases in which the blood of the thyroid artery and thyroid vein was compared were cases of hyperthyroidism with definite toxic evidences, while one of the seven cases was a case of nontoxic goiter (Tables II and III show findings in these cases).

There is a definite increase in the total number of leucocytes in the thyroid vein; this increase is due almost entirely to an increased number of lymphocytes, on the average an increase of $33\frac{1}{3}$ per cent in the blood of the thyroid vein. Only the case with the nontoxic goiter shows an increase in the leucocyte count of the thyroid vein, which is so small, that one may have to consider it within the limit of error.

The morphology of the blood of the thyroid artery compared with that of the peripheral blood shows practically no difference. Considering the findings of pathologists, of a general lymphatic hyperplasia in hyperthyroidism with lymphatic foci in the thyroid gland itself, we can assume that this increase of lymphocytes in the thyroid vein must be due to an actual formation of lymphocytes in the thyroid gland.

Phagocytic Ability of the Leucocytes.—The phagocytic power of the leucocytes was studied by an adoption of Hamburger's method.⁸ About 20 c.c. of oxalated blood was allowed to stand in test tubes, kept in an incubator at 37° ,

for four hours. The supernatant serum was first carefully removed, and then the leucocytes which accumulate on top of the erythrocytes. The leucocytes were then placed in normal saline, washed repeatedly with normal saline changes, and finally a suspension in normal saline was made. Five-tenths cubic centimeters of that suspension was brought into contact with 5 c.c. of the serum from the same individual and incubated for one hour at a temperature of 37° C. After one hour, 0.5 c.c. of india ink was added to the suspension and incubated again for one hour. The tubes were carefully shaken every ten minutes to maintain an equal suspension. From the incubator the tubes were then transferred to an ice box for two hours, and then smears made and stained by Pappenheim's method (Jenner and Giemsa combination). In the smears 500 neutrophilic cells were counted and the number of cells containing carbon particles were marked.

TABLE IV

CASE	PHAGOCYTOSIS OF NEUTROPHILES INCUBATED IN THEIR OWN SERUM	NO. OF CASE	PHAGOCYTOSIS OF NEUTROPHILES INCUBATED IN THEIR OWN SERUM
Normal	35 per cent	2	10 per cent
Normal	38 per cent	3	12 per cent
Normal	34 per cent	5	14 per cent
Normal	32 per cent	8	12 per cent
Normal	39 per cent	13	12 per cent
Normal	37 per cent	15	14 per cent
Average	35.8 per cent	Average	12.3 per cent

The neutrophiles of the normal individuals showed an average of 35.8 per cent of the cells having stored carbon particles, while only 12.3 per cent of the neutrophiles of the patients with hyperthyroidism showed storage of carbon particles (see Table IV). The question arose now whether we are dealing with a faulty type of leucocytes in hyperthyroidism, or whether the reduction in phagocytosis was due to some factor in the serum of the patient. For that pur-

TABLE V

NO. OF CASE	PHAGOCYTOSIS OF NEUTROPHILES INCUBATED IN NORMAL SERUM (GROUP IV) %
2	28 per cent

15	29 per cent
Average	29 per cent

pose the corpuscles of the patients were incubated in the serum of a normal individual (Group IV, to exclude possible precipitations) and the corpuscles of the normal individual (Group IV) were incubated in the sera of the patients. The neutrophilic cells of the patients, previously showing an average of 12.3 per cent phagocytosis, after incubation with the normal serum showed an average phagocytosis of 29 per cent. The normal corpuscles, originally having a phago-

cytic ability of 35 per cent, after incubation with the sera of the patients showed only 13.5 per cent phagocytosis (see Tables V and VI).

From these figures it can be seen that the phagocytic ability of the neutrophils in hyperthyroidism is definitely diminished, but this reduction of phagocytosis is not due to a faulty cell, but to the influence of the serum of the patient with hyperthyroidism, whether we are dealing with a deficient serum or whether there is a toxic inhibitory substance in the serum cannot be explained by the above data.

Experimental Hyperthyroidism.—Thyroxin was found to produce after 8 to 10 daily intramuscular injections of 1 mg. per kilo of body weight, definite

Chart I

signs of hyperthyroidism. Six cats were used for these experiments, 3 of them were given thyroxin, and 3 were used as controls. Daily blood studies were made on all animals for thirty days. The thyroxin injections were started on the seventh day and given daily until definite toxic signs developed (loss of weight, restlessness, diarrhea, etc.), then one or two injections were given weekly.

Erythrocytes.—Erythrocytes showed only slight changes. After a very slight initial rise during the third and fourth day after the injection, the erythrocytes came gradually down to a somewhat lower level during the third week after the injections had been started, leading to a slight degree of anemia. The control animals showed no changes.

TABLE VI

SERUM NO.	PHAGOCYTOSIS OF NORMAL NEUTROPHILES (GROUP IV) INCUBATED IN PATIENTS' SERUM
2	12 per cent
3	15 per cent
5	11 per cent
8	12 per cent
13	16 per cent
15	15 per cent
Average	13.5 per cent

Leucocytes.—The total number of leucocytes remained unchanged for about ten days after the injections were started, then they came gradually down to a definitely lower level. The differential count showed this reduction of leucocytes to be due to a reduction of the granulocytes. The lymphocytes showed coinciding with the reduction of the granulocytes, a mostly relative increase. The same is true of the monocytes. (Chart I shows the average percentage figures during these observations.)

RÉSUMÉ AND CONCLUSIONS

Kocher's blood picture was found to be present in practically all cases of hyperthyroidism. In addition as a striking observation an increase in the segmentation of the neutrophiles was noted, a shift to the right. Although the shift to the right may not be specific for a thyroid disturbance, just as Kocher's blood picture is not specific, it must still be considered as a considerable aid in the diagnosis, since it is not frequently observed in other pathologic conditions. The erythrocytes and thrombocytes are not strikingly diminished, but low normal or slightly subnormal figures are usually present. In other words the whole blood picture is that of a definitely depressed myeloid system. The same is apparently true in experimental hyperthyroidism. The diminished phagocytosis of the neutrophiles, being apparently due to an abnormal serum, together with the whole picture of myeloid depression all speak rather for a toxic influence of the thyroid gland. The lymphocytosis although mostly relative, is also absolute. Whether we are dealing with a general compensatory proliferation of the lymphatic tissue, or whether the proliferation is specific in the pathogenesis of the condition, cannot be decided so far. The presence of the proliferation, however, is definite and quite apparent in the comparison of the thyroid artery and the thyroid vein. I would like here to refer to the work of Hellmann, Heiber, Schlemmer, and others who believe the germinal centers of the lymphatic tissue to be a protective mechanism in the distribution of poisons and toxins. Aschoff in his excellent dissertation on the lymphatic organs⁹ does not quite accept this view, since there is not enough proof for the statements; he accepts, however, the possibility of such a protective mechanism.

MONILIASIS OF THE BILIARY TRACT*

REPORT OF CASE

JOSEPH M. MIRMAN, M.D., HARTFORD, CONN.

MONILIASIS is a disease which is caused by the *Monilia* fungi. There are over thirty species composing the *Monilia* genus.

Most of the organisms of the *Monilia* genus are widely distributed in nature and can be found on vegetables, fruit, wood, dead leaves, etc.

The name *Monilia* was first given by Hill in 1751 when he described a genus of fungi consisting of a pedicle supporting a number of naked seeds arranged together in a series like the beads of a necklace. Langenbeck in 1839 described the organism of a fungus found in the patches of Thrush in a patient who died from typhus and came to autopsy. Hansen in 1851 studied the fungi from rotting wood and found that in beer wort it produced abundant yeast cells which could produce a mycoderma skin-like infection in which the individual cells again elongated into a mycelium. But to Castellani we are indebted for his tireless investigation and classification of the members of the *Monilia* genus. He defines and describes this genus as follows:

"Oosporaceae, possessing in situ budding forms and mycelial threads which latter are often long and branched; in culture mostly budding forms, but sometimes filaments, in which thallospores of the blastospore type are formed. It ferments dextrose and often other carbohydrate media producing gas."

Castellani classifies the species according to color and fermentation as follows:

White, yellow, pink or red, and black.

Biochemically there are twelve groups:

1. Balcanica Group: gas produced in dextrose only.
2. Krusei Group: gas produced in dextrose and levulose.
3. Pinoyi Group: gas produced in dextrose, levulose, and maltose.
4. Metalondinensis Group: gas produced in dextrose, levulose, maltose, and galactose.
5. Tropicis Group: gas produced in dextrose, levulose, maltose, galactose, and saccharose.

*Received for publication, February 16, 1933.

6. Rhoi Group: gas produced in dextrose, levulose, galactose, and saccharose.
7. Bronchialis Group: gas produced in dextrose, levulose, maltose, and saccharose.
8. Guillermondi Group: gas produced in dextrose, levulose, saccharose, and raffinose.
9. Macedoniosis Group: gas produced in dextrose, levulose, galactose, saccharose, and inulin.
10. Pseudotropicalis Castellani Group: gas produced in lactose in addition to other carbohydrates.
11. Pseudolondiniosis Group: gas produced in lactose in addition to other carbohydrates, but not in lactose.
12. Zeylanica Group: no gas produced in any sugar.

The organisms vary in virulence and pathogenicity depending upon the species of the genus. In the human body they may be found on the skin surface, on the normal mucosa of the mouth and of the upper respiratory and the gastrointestinal tracts.

The *Monilia* genus has been shown to be the offensive organism of a number of *clinicopathologic conditions of the skin, mucous membranes of the mouth, vagina, lung, and intestine.*

Shelmire in 1925 summarized comprehensively cutaneous moniliasis under the heading "Thrush Infection of the Skin." Castellani gives a detail description of moniliasis involving the gastrointestinal tract, claiming that sprue is caused by *Monilia*. He also describes a case of purulent vaginitis caused by a *Monilia* genus.

It will be interesting to note that the etiology of sprue is still in a stage of medical controversy, though investigators like Ashford, Castellani, and Anderson have attempted to prove that *Monilia psilosis* is the offensive organism.

Moniliasis of the biliary tract has not been mentioned by the above investigators, neither has there been any article written on this subject.

However, in the course of my private practice I came across a case which I diagnosed clinically as "moniliasis of the biliary tract." The patient, female, aged forty-four years, resided in Connecticut for the past twenty-one years. While she appeared quite robust and well nourished, yet she complained of severe pain across her back, in her right shoulder and hip. She suffered with these pains for the past four years. Physical examination showed negative findings except for a slightly enlarged spleen and a tender mass in the right upper quadrant which was thought to be the gallbladder. The liver and the kidneys were not palpable. There was dryness in the mouth, but the tongue was clear. In intestinal moniliasis the tongue is coated, sore, and beefy. In this patient the bowels were constipated, and the stools were small in volume, hard and dark in color, while in intestinal moniliasis there is a pale, voluminous, foamy diarrhea. Blood Wassermann, urine, and routine blood work were negative. This patient had chills, fever, sweat on several occasions although smears for malaria, and blood cultures were negative.

The gallbladder was drained for diagnostic purposes. Before the sterile Rehfuess tube was inserted cultures were taken from the mouth, pharynx, and teeth. The result of these cultures was negative for fungi.

A sample of "B" bile was sent to the Connecticut State Laboratory for bacteriologic examination. The report showed that the bile contained *B. coli*, nonhemolytic streptococci, and yeast. On the culture the yeastlike form appeared in large amounts and was similar to *Monilia* morphologically. A portion of this culture was sent to the State Laboratory of Hygiene, Madison, Wisconsin. Doctor W. D. Stovall was kind enough to send a résumé of his report:

"Acid and gas in glucose, levulose, mannose. No fermentation on maltose, galactose, or saccharose. There is a distinct pellicle on the sugars which are fermented by this organism. Colony formation on malt agar was dull, dry and flat with mycelium production in forty-eight hours. This organism corresponds to the cultural relations of several strains of *mycoderma* which we have studied. It also corresponds to the cultural characteristics which we obtained when we studied *M.° Krusei* type."

The bile microscopically showed motile bacteria, bile crystals and pigments, fatty débris, epithelial cells and shreds.

The patient's gallbladder was drained for six consecutive weeks. Internally she was given heavy doses of potassium iodide and hexamethylamine. She was on a cholesterin poor diet.

It was interesting to note that the bile became free from fungi and bacteria, though it showed a few crystals and bile pigments. The patient has been relieved of backache and pain in the joints for over a year.

CONCLUSIONS

A case of moniliasis of the biliary tract is presented. The diagnosis was made by finding the fungus in the bile and on culture.

The treatment consisted of biliary drainage, potassium iodide, and hexamethylamine internally, and a cholesterin poor diet.

Patient has been symptom-free for over a year.

STUDIES ON RUBBER GLOVE STERILIZATION AND THE USE OF STERILITY INDICATORS*

ANSON HOYT, M.D., LOS ANGELES, CALIF.

FROM the beginnings of aseptic surgery the problem of adequate sterilization of the surgeon's hands has been of major importance. It soon became apparent that mechanical cleansing and chemical disinfection did not suffice, and trials were made of covering the hands with various substances. Methods,¹ such as the use of waxy materials or of cloth gloves impregnated with collodion or liquid paraffin, were devised. Rubber gloves were introduced into surgery by Halstead² in 1889. Their use was recommended by Robb in a textbook published in 1894, and they have been almost universally adopted since that time.

Rubber gloves are commonly sterilized by steam under pressure. This method has the advantage of being simple and efficacious, although it has not been standardized. Different practices are employed in wrapping the gloves, in stacking them in the autoclave, and in the times and pressures utilized for sterilization. The life of the gloves is relatively short, even with the best of care, as exposure to steam under pressure quickly reduces their strength and lessens their elasticity. It may easily be seen that any undue excess of steam pressure or time of sterilization will shorten the useful life of the gloves even more than is necessary.

The experiments to be reported, were planned in order to determine the minimum lengths of time that would be required, at various pressures, to completely sterilize heavily contaminated rubber gloves which had been wrapped in a uniform manner. At the same time an assay was made of the practical value of two types of sterilization indicators which are sold commercially. The indicators used were the Diack† and the Sterilometer.‡

The Diack is a small sealed glass tube containing a pellet of reddish wax-like material. When a certain temperature is reached, the enclosed pellet melts and changes color almost immediately. The temperature required for this change was found to be approximately 121° C., which corresponds to a little over 15 pounds of steam pressure. The complete melting of a Diack which has been placed near the center of a package of material to be autoclaved, is assumed to be indicative of the sterility of the material in question.

The Sterilometer is a strip of heavy paper on which has been printed a small figure representing a thermometer, the bulb and stem consisting of two sections, each of which is composed of a special cream-colored ink. On exposure to heat, these inks darken gradually. Complete blackening of the left-hand section, which is represented by the bulb and part of the stem, is said to

*From the Department of Bacteriology, School of Medicine, University of Southern California and the Laboratories of Unit I of the Los Angeles County General Hospital.

Received for publication, January 27, 1933.

†From A. W. Diack, 5533 Woodward Avenue, Detroit, Michigan.

‡From the Sterilometer Laboratories, 2308 Victoria Avenue, Los Angeles, Calif.

indicate the maintenance of a temperature of 230° F. for a minimum of approximately fifteen minutes, while the development of a corresponding color in the right-hand section means that 250° F. has been maintained for the same period of time. A Sterilometer, which has had both sections completely blackened by being near the center of a package of material that has been autoclaved, is assumed to indicate the complete sterility of the contents of the package in question. The blackening of the left-hand section alone does not necessarily indicate sterility. This section is merely supposed to act as a color standard and to show that the material in question has actually been autoclaved.*

The following organisms were used in the experiments: *Cl. oedematiens*, *Cl. welchii*, *Cl. septicum* (*Vibrio septique*), *Cl. sordellii*, *Cl. sporogenes*, *Cl. histolyticum*, *Cl. tetani*, *Cl. paratubulinum* A, *B. anthracis* and *B. subtilis*. The anaerobes were grown in chopped veal infusion broth for a period of at least two days before use. Microscopically all, save *Cl. welchii* and *Cl. tetani*, showed a prolific formation of spores. Growth was usually apparent in these latter cultures, however, even after they had been heated to 85° C. for fifteen minutes. *B. anthracis* and *B. subtilis* were grown on agar slants, and formed innumerable spores.

The gloves used were the gloves regularly employed in surgery at the Los Angeles County General Hospital. After contamination they were placed one in each side of a regulation glove book, and this was then wrapped in a double thickness muslin glove wrapper about 26 inches square. In most of the experiments four such packages were tied together before autoclaving. This made up a rather bulky bundle containing eight gloves, and sometimes a ninth glove was inserted in one of the glove books. The use of such bundles was an added factor of safety, as the penetration of steam was definitely slower than is the case in general practice, where gloves are wrapped in small packages and carefully stacked so as to facilitate the rapid penetration of steam.

The autoclave used was the instrument employed for the sterilization of bacteriologic supplies at the Los Angeles County General Hospital. This machine was carefully calibrated in respect to pressure and temperature. It was operated throughout, after a few preliminary experiments by one individual. In each experiment the glove bundles were placed as nearly as possible in the same portion of the autoclave. No preliminary vacuum was produced before the beginning of sterilization, but a special method, for quick elimination of the air, was employed in the later experiments. The door of the autoclave was left slightly open, and steam was allowed to escape at full pressure for a period of from one to two minutes. The door was then closed, and the steam pressure, used for sterilization, was attained very rapidly. This introduced an added factor of safety in that the time taken to attain a certain pressure was cut to the minimum, whereas, in general practice, this time may actually be a considerable factor in the process of sterilization.

Most of the experiments were conducted as follows: Two sterile swabs were

*The Sterilometer has recently been manufactured in a new and slightly different form. The ink in the bulb of the thermometer corresponds to that which made up the former left-hand section, while the stem consists entirely of the ink which composed the former right-hand portion. "The stem must turn black until it matches the color of the bulb," is printed in each indicator.

dipped into one of the spore-filled cultures and were then inserted into different fingers of a glove. A Sterilometer and, under certain circumstances, also a Diack were placed in the cuff of the glove. Eight, and sometimes nine, gloves, prepared in this manner, were wrapped as previously indicated and tied into one bundle. They were then autoclaved for a given time and pressure. The packages in the bundle were then opened, and the swabs were removed and cultured. The anaerobes were cultured in chopped veal infusion broth which had recently been boiled for a few minutes and then cooled. The swabs were inserted, rotated, and withdrawn, and sterile vaseline was poured over the surface of the medium. The aerobes were cultured in deep tubes of extract agar which had been melted and cooled to 40° C. Each culture was labeled with the name of the organism, the date, and the position which its swab had occupied in the bundle of gloves, i.e., whether in the outside or inside glove in an outside or inside package. One control was made directly from the original culture of each organism used. The actual Sterilometer was pasted opposite the record of its corresponding pair of cultures, and the condition of the Diack was recorded.

The cultures were incubated for at least four weeks before being discarded. Such a time is open to criticism as we realize that an occasional spore may lie dormant for an almost indefinite period before germinating. Meyer³ recommends incubating for a three months' period when conducting spore resistance tests on *Cl. paratubulinum* A. Meleney and Chatfield,⁴ however, regard fifteen days as an adequate incubation period in tests to check the sterility of surgical catgut, and we have chosen a time lying between the limits recommended above.

Growth in the anaerobic cultures was clearly evidenced by the production of gas, which forced the vaseline away from the surface of the medium. Growth in the aerobic tubes could be seen on the surface of the agar, and also, to a certain extent, in its depth.

A total of 73 experiments involving over 1,200 cultures, exclusive of controls was performed, all of the cultural work being done by the author. In the early experiments a different organism was used to contaminate each glove in the bundle. An effort was made to distribute the different organisms so that, in a series of experiments, each one would be placed near the inside and near the outside of the bundles an approximately equal number of times. It subsequently became evident, however, that *Cl. oedematiens* was by far the most heat-resistant of the organisms being used. In the experiments in which comparable numbers of the different cultures were employed, 14 out of 76 or 18 per cent of the cultures of *Cl. oedematiens* showed growth, whereas growth occurred in only 5 out of 76 or 7 per cent of the cultures of *Cl. sporogenes*, and the percentage of positive cultures of the other organisms was even less. For this reason all the gloves were contaminated with *Cl. oedematiens* in a number of tests which were performed at a later date.

EXPERIMENTAL RESULTS

In performing the experiments a given pressure was selected and a time which was thought to be inadequate was employed at first. This period was

then lengthened progressively, as growth in the cultures developed, until a time was found for each pressure at which all cultures remained sterile. These minimum sterilizing times were checked, with one exception, by at least three experiments, each involving eight or nine different cultures, and, in addition, three experiments in which *Cl. oedematiens* alone was used. This latter test was considered to be the most crucial of all. In two instances *Cl. paratubulinum* A was substituted for *Cl. oedematiens* in these latter experiments. The question arose as to whether dried spores might be more resistant to heat than are spores in the moist state. In answer to this, in at least one of each series of experiments, designed to check the minimum sterilization times at different pressures, dry gloves were contaminated with swabs on which the spores had been dried. These dried spores showed no more resistance to heat than did the corresponding moist spores under like conditions. Table I gives the results of this series of tests with respect to completeness of sterility attained at different times and pressures.

TABLE I
COMPLETENESS OF STERILIZATION ATTAINED AT DIFFERENT TIMES AND PRESSURES

20	10	4	63	3
20	15	7	118	0

An examination of the above table will show that the minimum sterilizing times attained for different pressures, under the experimental conditions employed, were as follows:

5 pounds	40 minutes
8 pounds	30 minutes
10 pounds	20 minutes
15 pounds	25 minutes
20 pounds	15 minutes

It is perfectly evident that a discrepancy appears between the times which were found to be adequate at ten and at fifteen pounds pressure. This discrepancy illustrated the important fact that the pressure recorded in an autoclave is not always a reliable index of sterilization. In order to insure adequate steam penetration the complete removal of air from the chamber is essential. For this purpose most autoclaves are equipped with an automatic chamber-drain valve and steam trap which allow the escape of air and water of condensation, but hold back most of the steam. It is entirely possible for such an

apparatus to get out of adjustment, in which case air may be retained and the temperature in the center of the packages being autoclaved may be raised relatively little. In such an event, when surgical materials are being sterilized, disastrous accidents may occur. As a check to offset this possibility the use of dependable sterilization indicators would seem advisable.

In two experiments, in which gloves were autoclaved at 15 pounds for twenty minutes, growth occurred in several cultures. The Sterilometers, which had been placed in the cuffs of the gloves that were incompletely sterilized, showed only a partial blackening of their left-hand portion and almost no change at all in their right-hand section. This condition of the Sterilometers was evident immediately upon opening the packages, and it gave presumptive evidence that the gloves in question might not have been completely sterilized, which, indeed, turned out to be the case. Furthermore a check of all the tests shows that in no instance did a completely blackened Sterilometer correspond with a glove that proved to have been incompletely sterilized.

The value of the Sterilometer is further illustrated by the following experience, which recently occurred in our laboratory. Several batches of culture media were found to be contaminated after having been autoclaved in the usual routine manner at 15 pounds for twenty minutes. For this reason it seemed advisable to check the functioning of the sterilizer. Two bundles, each containing four glove packages, were made up in the regular manner. A Sterilometer was placed in each glove bundle, and one was also tied on the outside of each bundle. One bundle was autoclaved at 15 pounds for twenty minutes in the exact manner that had been employed for the above sterilization of media. The second bundle was then sterilized in the same manner, with the exception that special care was taken, in this instance, to completely exhaust all air from the chamber of the autoclave.

Fig. 1 is a photograph of the actual Sterilometers used in the above two experiments. On the left are shown the indicators taken from the bundle which had been autoclaved with special care regarding the complete exhaustion of air. These Sterilometers are all either completely or very nearly completely blackened. They are all very much darker than the darkest Sterilometer that was associated with a contaminated glove in any of our experiments, which goes to show that the penetration of steam was sufficient, in this case, to insure complete sterilization of this bundle of gloves. The Sterilometers in the right-hand column were taken from the bundle which had been autoclaved in the manner routinely employed for culture media. The Sterilometer from the outside of the bundle shows an almost complete degree of blackening. The indicators from within the packages, however, are variable and incompletely darkened, demonstrating that the penetration of steam had been insufficient to insure adequate sterilization in this instance. Such a record should serve as a warning that an autoclave is not functioning properly, a state of affairs which might otherwise be entirely overlooked for a considerable period of time.*

*These experiments were subsequently repeated using gloves contaminated with *Cl. oedematis*. Several of the gloves, which were run in the improperly functioning autoclave, and which were associated with incompletely blackened Sterilometers were found to have been incompletely sterilized. Complete sterility was obtained in the case of those gloves which were associated with thoroughly blackened Sterilometers, a state of affairs which occurred only when all the air was exhausted from the autoclave.

The value of an indicator, such as the Diack, appears to be more problematical. In the experiments summarized in Table I, a melted Diack was always associated with complete sterilization of the glove in question. The Diacks employed in this study, however, did not melt at all until a temperature of approximately 121° C. was reached. For this reason they could not be used as indicators when gloves were autoclaved at low pressures. On the other hand they melted almost immediately when the requisite temperature was attained, and therefore, theoretically at least, did not necessarily give evidence concerning the time factor involved in the complete sterilization of spores at any given temperature.

It, therefore, seemed desirable to further assay the value of this indicator, and a new type of experiment was devised. Two gloves were contaminated with *Cl. oedematiens* and a Diack and a Sterilometer were tied together and

Fig. 1.

placed in the cuff of each of them. The gloves were wrapped in a small package containing only one glove book. They were autoclaved at a high pressure for a short time, following which cultures were made in the manner previously indicated. A number of these experiments were performed, the times in the autoclave and the pressures attained being varied. The protocol of one such experiment is here given:

Total time in autoclave	3½ minutes
Highest pressure attained	19 pounds
Diack	melted
Sterilometer	incompletely darkened
Culture from glove	growth

Results such as this were obtained on two occasions. In these tests the efficacy of the Sterilometer was again upheld, whereas it was shown that it is possible to demonstrate instances in which the melting of a Diack will not serve as an indicator of complete sterility.

The importance of the penetration of steam in sterilization is also illustrated by the following results: In 34 instances of cultures showing growth, a record was kept of whether the swabs, from which the cultures were made, had been taken from an inside or an outside package. Of these, 7 swabs were taken from outside packages, whereas 27 came from inside ones.

DISCUSSION

It is of interest to compare the results of the experiments reported above with previous work on the heat resistance of various spores. Bigelow and Esty⁶ reported that some thermophilic organisms would withstand considerably more heat for a given time than did any of the spores employed in our work. It is obvious that the sterilization indicators used by us would probably have been inadequate as an index of sterility if the gloves had been contaminated with spores of these thermophiles. These organisms, however, do not appear to be of any consequence as a surgical problem.

The spores of *Cl. parabotulinum A* are generally considered to be more heat-resistant than are those of any other organism pathogenic to man. Meyer,³ in 1931, quoting the work of Esty and Meyer⁷ in 1922, reports the following figures as indicating the "maximum heat resistance of *Cl. parabotulinum* spores produced in a pea peptic digest medium under optimum conditions of growth:

"33 to 36 minutes at 110° C. or 6.1 pounds
11 to 12 minutes at 115° C. or 9.8 pounds
2 to 8 minutes at 120° C. or 14.1 pounds"

Although this organism can hardly be said to be of surgical significance we decided to check the Sterilometer against these maximum survival times. These indicators were therefore sterilized free in the autoclave at the longest time intervals recorded in the above table and at the corresponding pressures. None of these Sterilometers were completely blackened. It therefore appears safe to assume that a completely blackened Sterilometer would indicate complete sterilization of a glove even though it had been contaminated with an organism as resistant as the above strains of *Cl. parabotulinum A*.

Most of the organisms employed by us may be said to be of great surgical significance. Fortunately their heat resistance appears to be relatively low, when compared with that of the above bacteria. Esty and Meyer⁷ reported that the heat resistance of a number of the anaerobes associated with gas gangrene was markedly less than that of *Cl. parabotulinum A*. Murray and Headlee⁸ found that spores of *Cl. tetani* would be effectively destroyed in physiologic saline at the following times and temperatures:

25 to 60 minutes at 95° C.
10 to 25 minutes at 100° C.
5 to 10 minutes at 105° C.

Murray⁹ found the following times and temperatures effective for the destruction of anthrax spores under like conditions:

15 to 45 minutes at 90° C.
10 to 25 minutes at 95° C.
5 to 10 minutes at 100° and 105° C.

Finally Headlee¹⁰ reported that spores of *Cl. welchii* would be destroyed under like conditions in

35 minutes or less at 90° C.
15 minutes or less at 95° C.
10 minutes or less at 100° C.

From the work reported it seems that a completely blackened Sterilometer may, when properly used and interpreted, be regarded as an indicator of the adequate sterility of rubber gloves. This is especially the case inasmuch as this indicator has been successfully checked against more than 400 cultures of *Cl. oedematiens*, which appears to be a highly resistant organism. The penetration of steam has been shown to vary considerably when glove packages are packed closely together. For this reason it is essential that the individual glove packages be carefully arranged in the autoclave to permit the maximum access of steam to each. We feel that gloves may be safely sterilized at 10 pounds for thirty minutes, 15 pounds for twenty minutes, or 20 pounds for fifteen minutes, provided that the autoclave is functioning properly and that the penetration of steam is sufficient. A suitable indicator, if placed in the center of each glove package, should act as an adequate check as to the efficacy of the sterilization obtained under the above conditions.

SUMMARY

Rubber gloves were contaminated with different spore-forming organisms, wrapped in a uniform fashion, and autoclaved at varying times and pressures. They were then tested for sterility.

Minimum sterilizing times for gloves, autoclaved at varying pressures under the experimental conditions employed, were determined.

Cl. oedematiens was found to be the most heat-resistant of the organisms used.

The values of two indicators of sterility, the Diack and the Sterilometer, were checked in connection with these glove sterilization experiments.

The Sterilometer, when properly used and interpreted, was found to be an adequate indicator of the sterility of the gloves in question.

Gloves may safely be sterilized at 10 pounds for thirty minutes, 15 pounds for twenty minutes, or 20 pounds for fifteen minutes, provided that the autoclave is functioning properly and that adequate penetration of steam has occurred.

VARIABILITY IN THE CORN COMPONENT OF A RACHITOGENIC DIET

ROBERT S. HARRIS, B.S., AND JOHN W. M. BUNKER, PH.D., BOSTON, MASS.

IN A PREVIOUS communication¹ we recommend that before yellow corn (maize kernels) be used in a rachitogenic diet, it should be stored for at least six months after grinding. We have found that this procedure reduces variations in the intensity of rickets and increases the severity of the rickets produced in rats on the Steenbock diet No. 2965. Bourdillon and coworkers² have recently substantiated this finding.

Further work in these laboratories supports our original findings and confirms our opinion that the content of antirachitic substance in corn is responsible for the variations. This work consists of testing forty samples of yellow corn obtained during June and July, 1931, from nineteen different states of the United States. Five pounds of each sample were finely ground and stored for six months at room temperature in white, soda-glass, cork-stoppered bottles. An equal portion of each sample was stored under the same conditions but ground at the end of the storage period rather than at the beginning. After storage, a sample of each corn, stored after grinding and ground after storing, was incorporated as the sole corn component of a batch of the Steenbock ration.

These eighty rations, differing only in respect to their corn component, each prepared with the same care to secure uniformity in compounding, were fed for the usual twenty-one days to Wistar strain albino rats, of average initial weight 50 to 55 gm. in groups of four each. Every animal was weighed each second day throughout the test.

The degree of rickets was determined by the "line test" and confirmed by x-ray. The results are expressed as +, ++, +++, +++++, in increasing order of severity. The average degree of rickets for each group is displayed in Table I and in Fig. 1.

Chemical determinations on the forty corn samples included moisture, ash, fat (petroleum ether thirty-hour Soxhlet extract), calcium (modified method of Neumann³ and of Treadwell and Hall,⁴ and phosphorus (modified methods of Neumann³ and Johnson⁵). Condensed results are given in Table I. It may well

be that there are phosphorous linkages which vary in assimilation properties. We are analyzing for these various phosphorus fractions and will report on them later.

The most significant chemical constituents, because of the known importance of the Ca/P ratio in this diet, are calcium and phosphorus. In our analyses, the size of the sample taken (10 gm.) proved insufficient to give a quantitation of calcium. Check determinations made subsequently upon larger samples by us, and the subsequent oral presentation of corroboratory work by Holmes,⁶ showing that the expectancy for calcium in corn is of the order of about 0.05 per cent, make it obvious that in this ration, in view of its large proportion of added

Fig. 1.

CaCO_3 , the calcium constituent of the corn itself has an insignificant effect upon the total Ca/P ratio of the diet as compounded.

Phosphorus determinations showed that there is considerable variation in the amount of this element in the different samples of corn. This variation was so large that the Ca/P ratio of the diet compounded with sample No. 40 was 3.98/1, and 6.7/1 with sample No. 3. The degree of rickets produced by these two samples, when used freshly ground, was "none" and "one +," but when stored after grinding it was "two -" and "three -" respectively. While actual determinations of phosphorus were not made upon the same corn sample both before and after storage, there seems no valid reason for a decrease in total phosphorus (on a dry basis) during storage, and it is therefore assumed that the total phosphorous content of the stored ground corn represents the content of a similar sample stored in the whole kernel. An examination of Fig. 1 indicates that neither the total phosphorus nor the Ca/P ratio of the

finished diet correlates with the variations in degree of rickets produced. In this connection, it may be pointed out that our results do not entirely agree with those reported by Brown and coworkers⁷ in which difficulty in producing rickets upon a ration containing more than 0.25 per cent P is indicated. We heartily agree with their thesis that the percentage phosphorus in rachitogenic diets should be stated.

In view of the evidence herewith presented, we conclude that the presence of a significant amount of antirachitic substance definitely affects the degree of rickets produced and causes wide differences in the rachitogenic properties of the corns tested.

It seems to us a reasonable premise that in testing a substance for its antirachitic potency, the animals at the start of the feeding period should be in a condition caused by the absence of the factor which is to be assayed, not in a condition caused by a partial deficiency of this factor. In testing the ability of a substance to cure rickets, the animals should be rachitic, not partially rachitic. Judged by this criterion, if "freshly ground" corn were used by each of forty laboratories which had been supplied with samples of corn identical with ours, at the end of twenty-one days only one laboratory would have animals with severe rickets, 14 laboratories would have animals with moderate rickets, 13 would have animals with fair rickets, 6 would have animals with slight rickets, and 6 would have failed to produce any rickets at all.

Even if these corns had been ground and then stored before using in the diet, although the results would have been favorable in a larger number of cases (12 samples supporting the production of satisfactory 4+ rickets, 11 giving 3+, 14 causing 2+, 2 producing rickets of 1+ degree, and only 1 failing completely to cause a detectable rachitic condition), still it must be evident that this preliminary grinding and storage for six months is merely a palliative and not a remedy and does not relieve the user of the necessity of preliminary assay of his corn sample.

Space prohibits the discussion of the varying rates of growth with the samples tested and whether this has any bearing upon the results. We can find no correlation between our growth curves and the severity of rickets developed and conclude that the relation is negligible if present at all.

The development of a rachitogenic diet more reliable than those containing variable substances such as corn, is necessary. We have inaugurated experiments toward this end.

THE RELATION OF BLOOD GLUTATHIONE TO THE HEMOGLOBIN AND AMOUNT OF RED CELLS*

RAWSON J. PICKARD, M.D., AND CHARLES S. MARSDEN, JR., SAN DIEGO, CALIF.

GLUTATHIONE, found widely in plant and animal tissues, is the chief of the sulphhydryl compounds which have the reversible property of accepting and giving up hydrogen. "The autoreduction and oxydation of glutathione depend on the simultaneous presence of catalytic metals and an additional factor" (Wurmser), conditions found only in living cells. This faculty constitutes an intracellular respiration. In the blood, glutathione exists only in the cells and might, therefore, be expected to follow their fluctuations. We find, however, that it does not do this, that the amount of glutathione even in severe anemia is usually near the normal level, so that its quantity relative to the bulk of the containing cells is increased. The glutathione is, therefore, independent of the hemoglobin, and is rather connected with the metabolism of the erythrocyte as a living cell. Our work suggests that glutathione is larger in amount proportionately in young cells and a normal glutathione in an anemic blood is evidence of replacement.

To learn the relation, if any, of glutathione to hemoglobin, to number of red cells, cell volume, and to the other reducing substances of the blood, we chose for study a series of anemic bloods. In pathologic bloods the wide deviations of the various findings would throw into light immediately any quantitative connection between any group of the constituents, while with the normal of a biologic substance the narrower limits of normal deviation might place some of the elements examined in a specious relationship expressible by a simple figure and made plausible by statistical correlation. While we were working, there appeared the paper of Woodward and Fry¹ on blood glutathione (GSH) in which they computed Gabbe's quotient, $\frac{\text{GSH}}{\text{R.B.C.}}$, and added one of their own, $\frac{\text{GSH} \times \text{Hb}}{\text{R.B.C.}}$. In 23 bloods Gabbe's quotient ranged from 4.9 to 9.1, the quotient of Woodward and Fry from 5.3 to 8.2. This would hardly prove any relation between these elements in normal blood. Our tables of anemic bloods show still more clearly this lack of quantitative relation.

Glutathione† was determined by direct titration with N 1/1,000 iodine using starch as internal indicator, as advised by Delaville and Kowarski,² adding 2 c.c. of 25 per cent KI to 10 c.c. of tungstate filtrate as suggested by Perlzweig and Delrue.³ The iodine solution was checked by titration of a

*From the Research Department, Grace Deere Velle Clinic, Carmel, Calif.

Received for publication, March 1, 1933.

†Glutathione received through the courtesy of Dr. E. M. MacKay.

standard glutathione solution. We used the ordinary 1/10 tungstate blood filtrate. The stability of glutathione in this filtrate will appear in the note on tissue filtrates.

The hemoglobin was determined by the Newcomer method (B. & L.), a method that is practical and is as accurate as the Van Slyke oxygen capacity method when the Newcomer glass plate has been standardized by the latter,⁴ and with which duplicate tests check so closely as to be unnecessary. As a percentage we report the hemoglobin by Williamson's normal of 16.92 gm. per 100 c.c. for men, 15.53 gm. for women. This seems to be accurate for our locality, San Diego. The careful work of Osgood and Haskins has shown their normal of 15.8 gm. for men, and 13.7 for women to be correct for Oregon where their work was done, but use of their normals made the color and volume indices too high for the clinical picture in our cases. The wide variation of the red cell count and of the hemoglobin in health makes any standard quite arbitrary. The difference between men and women's blood is really a difference perhaps occasioned by the difference between their muscular activity. Sedentary persons should probably be appraised by the normal female standard.

As volume index, $VI = \frac{\text{per cent normal cell volume}}{\text{per cent normal cell count}}$, we took 5 million as normal red cell count, and 48 per cent (Sanford⁵) as normal volume of packed cells. We tried out the volume index by the method of Osgood, Haskins and Trotman,⁶ $VI = \frac{\text{per cent cell volume}}{\text{per cent R. B. C.}}$, when the volume of packed red cells per 100 c.c. blood, calculated to a red cell count of 5 million (men 41 per cent, women 43 per cent packed cells) is taken as 100 per cent cell volume for the sex, and when 5 million per c.mm. is taken as 100 per cent red cells, but this index was considerably too high for our locality, giving with the bloods of the secondary anemias in Table I an average of 1.1; with the anemias from hemorrhage, Table II an average of 0.9; with the subnormal bloods in Table IV, the average was 1.1.

The color index was calculated by dividing the percentage of 5 million cells into the percentage of hemoglobin, obtained as above. So many indices have been advised for clinical blood work that it seemed best to choose these two which are better known and simpler. Both are subject to inexplicable variations. The rule is given that if either the color or volume index is over 1.25, the anemia is pernicious. There are many exceptions to this among our cases.

The apparent blood sugar determined by the Folin-Wu method, as is well known, includes a nonglucose sugar in small amount, the glucid X of Fonte's and Thivolle, saccharoid of Benedict, which is not glutathione.⁷ The nonglucose reduction beyond that of the Folin-Wu figure, as measured by the Ionesco ferrieyanide technic⁸ in the same tungstate filtrate is reported in terms of glucose. This, the Y-reduction first reported by Pickard, Pierce, Marsden, Tanaka and Townsend,⁹ includes the reduction given by glutathione. One-half the figure for the amount of glutathione in milligrams per 100 c.c. subtracted from the Y-reduction (excess of the Ionesco technic over the Folin-Wu,

as glucose) leaves the variable part of the Y-reduction, due to unknown substances which are greatly increased in certain pathologic conditions. Glutathione is separated from the other part of the Y-reduction by the preparation of unlaked blood filtrates (Folin), it being then precipitated with the red cells.¹⁰

The bloods are arranged in the tables in order of increasing amounts of glutathione. Table I gives the findings in 23 cases of secondary anemia of

either hemolytic or aplastic type. The glutathione is normal except in four cases and in these bloods the anemia is not particularly marked, but in all four the diseased condition is of several years' duration. Table II lists 10 cases of anemia from hemorrhage. The patient in Case 31 had a glutathione of 4.2 mg.; a week later (blood 40), with a rise in the red cells from 1.6 to 2.5 millions, the gluta-

thione was normal, 30 mg. per 100 c.c. Assuming 30 mg. glutathione and 5 million cells as normal, the concentration of glutathione in samples 31 and 40 is respectively 50 per cent and 200 per cent of the normal concentration. Calculated to a normal cell volume of 46 per cent the glutathione concentration is 64 per cent (31) and 250 per cent (40). In the erythrocytes put in circulation immediately after hemorrhage, the glutathione was exceptionally low. Its restoration to normal in a week would seem indicative of its importance. The same drop after hemorrhage occurred in Case 51 (Table VI). Unfortunately we were unable to obtain follow-up specimens on other patients in Table II. In these

bloods of anemia from hemorrhage the glutathione follows somewhat the loss in cells and hemoglobin. In nearly all the bloods in Table I, the glutathione is in the normal range of 20 to 40 mg., average 30 mg., and its importance to the metabolism of the erythrocyte can be deduced from this together with the absence of any ratio between the amount of glutathione and the number of cells, amount of hemoglobin, cell volume percentage, or the amount of the other reducing bodies. Graphs drawn experimentally to trace any trend or grouping of the GSH and other blood findings showed only the widest divergence. We believe that the tabulated results bear out the idea that the hemoglobin and cell volume percentage should be reported in their actual amounts,

as are the red cell count and the blood chemical findings, rather than as a percentage of normal averages, which latter, like the indices, can be misleading. The clinician should base his diagnosis on findings referred to the normal range for the individual type. Ratios between the findings not apparent on inspection are apt to be misleading or unimportant.

Table III gives the glutathione in 7 cases of anemia diagnosed as pernicious; this is not enough from which to draw any conclusions but the low glutathione is noticeable. The bloods in Table IV are mostly in the lower limit of normal but were placed there because of apparent good health. None of the eight were doing any regular active muscular work. Except the patient in

Case 61 all were regular users of alcohol, the distinction of 62 and 64 as "alcoholic" was because they were exceptional in the amount consumed daily, the patient in Case 64 using 300 c.c. (as absolute alcohol) daily, and it was thought that this might influence the blood sugar, in both cases at the upper normal limit.

We were able to follow two cases. Case I was a young man, a college student in poor health in that he easily became exhausted. Physical examination was negative except for a basal metabolic rate of minus 16. His father died of Hodgkin's disease. While his blood smears were negative, the high color and volume indices suggest pernicious anemia. The blood glutathione remained low (Table V). There is evidently a severe metabolic disturbance.

The low basal rate may be due to the low glutathione and resultant lower intracellular metabolism and not to the thyroid.

Case 51, a woman in midlife, was in a run-down condition, asthenic, nervous, worried and suffering from insomnia at the time of the first examination when the Y-reduction was high, 106 mg. The high blood indices suggested pernicious anemia; there were no nucleated cells. The second examination was like the first except that the patient was feeling stronger and sleeping well and the Y-reduction was then normal, 13 mg., of which glutathione accounted for 12 mg. The high red count with lower hemoglobin on December 6 (Table VI) was due to severe menstrual loss; she had been on liver and iron treatment for a week. The glutathione fell to 8.7 mg. with the hemorrhage, and the color index from 1.4 to 0.9.

The Y-reduction was originally calculated as a difference in reduction between different filtrates and reduction technics, and was then found to average about 40 mg. per 100 c.c. in normal blood.⁹ There have not been many normals examined since the use of the Ionesco technic as a comparison with the Folin-Wu in the same tungstate filtrate. As Fabre¹¹ says, the difficulty of dissolving the sulphydryl derivatives tends to demonstrate that reduced glutathione does not exist in a free state, but in a potential form in the cells of the organism. This is borne out in that copper solutions are not reduced by the glutathione in the blood, while glutathione added to blood before precipitation gives an added reduction with the Folin-Wu (20 per cent as glucose) and Ionesco technics (50 per cent, as glucose) and is also quantitatively recovered

by the iodine titration and in the increase in nonprotein nitrogen.¹⁰ The Ionesco technic shows the reduction of true glucose and of glucid X, as does the Folin-Wu, and in addition the reduction of the glutathione of the cells together with a reduction due to unknown substances.¹⁰ We believe from the present work that the normal fasting Y-reduction nearly approximates that part of the Y-reduction due to glutathione. Certainly a Y-reduction of over 25 mg. shows an increase in the part due to the unknown substances which are increased, or retained, especially in kidney disease.

The possibility that the quantity of glutathione in a tissue might serve as an index to its metabolic activity is suggested by the work of Blanchetière

*During severe menstrual hemorrhage.

and Mélon, cited by Wurmser,¹² using dog and rabbit tissues. Mme. Boucher-Firly found that the total amount of glutathione in eels diminished as they grew older, and there is a parallelism between the amount of glutathione and the oxygen consumption.¹³ Murray found the same progressive diminution in glutathione in chicken embryo. His work is cited by M. Labbé, H. Labbé and Nepveux in a résumé of the work done on the clinical aspect of the glutathione content of blood and other tissues.¹⁴ They state that neither fasting nor diet change the glutathione in the blood nor is there any connection between the quantity of glutathione and changes in the basal metabolism. They think that "the mechanism of the action of glutathione is extremely complex, that it is probable that the sulphydryl bodies act at the level of certain stages of the degradation of acid chains where there is no immediate or simultaneous

effect on the terminal stages such as glucose, urea or uric acid." They found a low blood glutathione in many patients with disturbed nutrition: gout, diabetes, cirrhosis, obesity, half or less of the 21 mg. per cent which they find in normal blood, following the technic of Tunncliffe modified by Randoïn and Fabre.

That the comparison with the normal glutathione of the tissue may be an index to the restorative capacity in pathologic conditions is suggested by our tables of anemic bloods. Table VI gives the glutathione content in cavy and human tissues, including three cancers. We macerated the tissues in distilled water for an hour, then precipitated with tungstic acid to obtain a 1/10 filtrate as with blood. There has been some criticism of the tungstate extraction of glutathione. Following Tunncliffe most of the work with glutathione has been done on triochloroacetic acid filtrates. Repeated tests on our tissue filtrates either alone or standing on the tissue and continuing the ex-

traction, checked so closely after hours and even days that we give the result of one test in which the extraction continued two weeks and the glutathione determination was the same within the limits of error. The tungstate extraction seems to be immediate and complete. For these reasons we do not think the criticism of tungstate filtrates for glutathione are valid. We tried the sulphosalicylic acid filtrate advised by Woodward and Fry but did not get a distinct end-point with the iodate titration, and the results were lower than with tungstate and iodine.

With guinea pig liver and striated muscle our results correspond with those obtained by Blanchetière and Mélon. In the embryo cavy the liver is a tremendous storehouse for glycogen, nearly 2.8 per cent as glucose. The fetal liver has a low glutathione content compared to that of the adult liver when the digestive function is active. The glutathione in the pregnant uterine muscle of the cavy was much higher than that in the smooth muscle examined by the French investigators. The highest glutathione we found was in an embryonal carcinoma of the testis, and except for liver the largest amount

found in other tissues was in parts of an actively growing cancer of the breast. This is in accord with the findings of Thompson and Voegtlin (cited by Wurmser). Their statement that these tumors seem to collect glutathione and that it diminishes in the rest of the organism is contradicted by Labbé and Nepveux, and for the blood at least is not sustained by Woodward and Fry, who found a normal blood glutathione in their six cancer cases. In the embryonic carcinoma of the testicle, cancer of the breast, papilloma and other tissues the area in the microscopic picture occupied by nuclei is in direct ratio with the glutathione content of the tissue, suggesting that this substance is chiefly in the nuclear protoplasm. Fat, containing almost no cytoplasm, had the lowest glutathione, almost as low as was given by the dense white fibrous tissue from a chronic mastitis. Tissue activity and the amount of glutathione seem to correlate to such an extent that the latter may be taken as an index to intracellular metabolism.

SUMMARY

The blood glutathione is necessarily lowered when there is a sudden loss of blood, but its amount is early restored to the normal preceding that of the number of red cells and the hemoglobin. There is no quantitative relation between the hemoglobin and the glutathione of the blood. Although the glutathione of the blood is part of the content of the red cells, its quantity does not follow variations in either the cell count or the cell volume. The average amount of glutathione in 2 patients with nonhemorrhagic secondary anemia (Table I) was 24.9 mg.; excluding the 5 bloods with glutathione under 20 mg., the average was 28.5 mg. For the bloods taken after severe hemorrhage (Table II) the average glutathione was 17.1 mg., average red count 2.3 million, average cell volume 17.5 per cent. Calculated to a red count of 5 million, the glutathione would be 37 mg., a 23 per cent excess concentration in the cells, and to a normal cell volume of 46 per cent, there is a 150 per cent glutathione concentration. This gives added emphasis to the findings in Case 1, Table V. In this patient the glutathione as calculated for 5 million cells is 8.0, 8.5, 9.5, 5.8 mg. for the four examinations, averaging only 27 per cent of the normal concentration as to cell count, and 26 per cent of the normal as to cell volume. The persistently low glutathione in the blood of this patient, asthenic, but without definite physical findings, constitutes a deficiency in cell protoplasm new to medical literature.

THE INACTIVATION OF GROWTH HORMONE*

II. AS A RESULT OF EXPOSURE TO AIR

H. S. RUBINSTEIN, B.S., M.D., BALTIMORE, Md.

IN THE course of experiments dealing with the effect of growth hormone upon the brain-weight-body weight ratio¹ it was noted that in order to maintain continuous body growth in rats (*Mus norvegicus albinus*) it was necessary to use fresh extract almost every other week. This became necessary because after an initial growth stimulating effect, it was noted that the extract soon lost its potency. It therefore became quite an interesting problem to determine the factors causing this loss of potency of the extract and recently this laboratory reported improper refrigeration to be one of these.²

As a result of this, it was found advantageous to place a few drops of phenolphthalein as an indicator into each bottle of growth hormone and to use the extract only as long as the P_H was maintained at approximately 8.3. The addition of phenolphthalein led to a rather interesting observation; namely, that pouring the extract into a beaker prior to administration caused a fading out of the red color with a consequent loss of alkalinity. At first this phenomenon was believed to be due to acid fumes in the air since our laboratory is situated in an industrial center.

In order to rule out such an atmospheric factor, 30 c.c. of growth hormone were placed in an open beaker within a refrigerator whose temperature was kept at 10° C. In another beaker, were placed 30 c.c. of meat extract which is ordinarily used for control injections. The alkalinity of each extract was just sufficient to give a pink tinge to phenolphthalein (P_H 8.3). These were

*From the Neuroanatomical Laboratory of the Department of Anatomy, University of Maryland Medical School.

Received for publication, January 4, 1933.

then allowed to stand, thus exposed to the cold air of the ice box, for twenty-four hours, at the end of which time, the growth hormone solution was completely decolorized, while the meat extract maintained its color. The only single factor which could possibly have decreased the alkalinity of the growth hormone was air, since refrigeration was adequately maintained. Furthermore, as long as the extract was kept stoppered no diminution in its alkalinity could be noted.

If allowed to stand long enough, this alkalinity will be decreased even to the point of becoming truly acidic, since Morrell³ checking up on some of our findings noted in one case a drop in P_H from 8.3 to 6.76.

The necessity for keeping the solutions well stoppered even during injections becomes quite apparent since, as in the case where inactivation is the result of inadequate refrigeration, growth effects can be obtained only with definitely alkaline material.

CONCLUSIONS

1. Growth hormone is active only so long as it is alkaline.
2. Alkalinity is diminished and even lost when the hormone is exposed to the air.

Acknowledgment: The author wishes to express his gratitude to Dr. Carl L. Davis, the head of this Department, through whose kind cooperation and excellent advice this work is being carried on.

LABORATORY METHODS

THE DETERMINATION OF HEMOGLOBIN BY THE IRON CONTENT METHOD*

RUSSELL L. HADEN, M.D., CLEVELAND, OHIO

THE presence of iron in blood was first demonstrated by Menghini of Bologna in 1747,¹ and for more than a century the study of this problem has excited much interest. Quantitative analyses were made by Denis in 1830,² and quite accurate estimations were accomplished by others before 1850. The early investigators obtained a remarkable uniformity of results³ by working with relatively large amounts of blood.

After the isolation of hemoglobin in crystalline form by Funke in 1851,⁴ analyses of hemoglobin crystals by Hoppe-Seyler⁵ showed sufficient iron in the crystal to account for all the iron found in whole blood. In the first monograph on hemoglobin, published in 1871,⁶ Preyer compared the quantitative determination of hemoglobin by the spectroscopic, iron content, and colorimetric methods and found that they gave identical results. In 1877,⁷ Malassez' first paper on clinical methods for estimating hemoglobin described three chemical methods, by determination of the iron content, of the oxygen capacity, and of the hematin content of the blood. Even at this early date in clinical hemoglobinometry, however, the colorimetric method already was well established and numerous procedures were in use. The iron content method was little used for many years, although the ferrometer described by Jolles in 1898⁸ was employed to some extent and papers on the iron content of the blood appeared from time to time.

In recent years, there has been much improvement in the methods for estimating hemoglobin and renewed interest in the two available accurate chemical methods. This has been due largely to the development by Wong⁹ of a simple and precise microchemical method for the determination of iron and also to Van Slyke's¹⁰ development of a blood gas apparatus in which oxygen capacity of the blood can be determined correctly by using small quantities of blood. Laboratory workers agree that all hemoglobinometers should be standardized by some accurate chemical method, and the oxygen capacity method has so far been the one preferred. Blood gas analyses, however, require experience and special apparatus. The determination of iron is a simpler procedure, and if it yields results as accurate as the measurement of hemoglobin by the oxygen capacity method, it should be of equal value as a method of standardization and

*From the Cleveland Clinic.

Received for publication, April 5, 1933.

also should be available for special laboratory estimations of hemoglobin. If the estimations of hemoglobin by the iron content and by the oxygen capacity methods check within the limit of error, it is apparent that the ratio must be a constant one and that the iron content is an accurate measure of the amount of hemoglobin present. For all practical purposes, the iron content of the whole blood may be considered an indicator of the hemoglobin just as the oxygen capacity is taken as a measure of hemoglobin.

The oxygen capacity method determines all the hemoglobin present in blood except the small amount combined with carbon monoxide. Gettler¹¹ has shown

that the carbon monoxide content of the blood is greater in city than in country dwellers but is never sufficient to interfere with clinical determinations of hemoglobin. Riecker¹² found a small amount of iron (1.1 ± 0.022 mg.) in the blood plasma of normals. The remainder of the iron present in blood is in the hemoglobin molecule. In a recent article Reich and Tiedeman¹³ have disputed the value of the iron content of the blood as a measure of hemoglobin and have concluded that the ratio between hemoglobin and iron is not constant; they used in their study a colorimetric estimation of hemoglobin.

From time to time over several years I have determined the iron content and the oxygen capacity of specimens of oxalated blood. Lindsay, Rice and Sellinger,¹⁴ and Kennedy¹⁵ have made similar studies. The values for hemoglobin, when calculated in these two ways, have always checked closely and well within the limit of error. I have compiled the data so far available in Table I. In 36 determinations, the mean hemoglobin by the iron content method is 13.33 gm. and by the oxygen capacity method, 13.34 gm. These results indicate that there is no variation in the iron hemoglobin ratio not accounted for by errors in estimation, and prove that the iron content is as accurate a measure of the hemoglobin as is the determination of the oxygen capacity.

My early determinations were made by the Dupray¹⁶ modification of the original Wong method. In this procedure, perchloric acid is added to facilitate digestion and nitric acid to prevent fading of the iron sulphocyanate. Kennedy¹⁵ suggested the digestion of the blood with perchloric and sulphuric acids, and subsequent extraction of the digested material with sodium sulphocyanate and amyl alcohol to prevent fading. In Wong's new method,¹⁷ the iron is split off from the hemoglobin with sulphuric acid and potassium persulphate, and the interfering proteins are precipitated with tungstic acid, and sodium sulphocyanate is added to the filtered solution. The potassium persulphate prevents the fading of the iron sulphocyanate for a long time. I have found no difference in the results obtained by different methods. The new method of Wong¹⁷ is as follows:

REAGENTS REQUIRED

"All the reagents except the standard must be iron-free as shown by blank tests.

"1. Concentrated Sulphuric Acid.

"2. Sodium Tungstate.—Dissolve an appropriate amount of good grade sodium tungstate to make a 10 per cent solution.

"3. Saturated Potassium Persulphate.—Introduce into a small glass-stoppered bottle about 7 gm. of pure potassium persulphate and shake up with 100 c.c. of distilled water. The undissolved portion settles on the bottom to make good any decomposition upon standing.

"4. Potassium Sulphocyanate.—Prepare approximately a 3 N solution by dissolving 146 gm. of pure potassium sulphocyanate in distilled water to make 500 c.c. Filter, if necessary. Add 20 c.c. of pure acetone to improve its keeping quality.

"5. Standard Iron Solution.—Weigh accurately 0.7 gm. of crystallized ferrous ammonium sulphate and dissolve in about 50 c.c. of distilled water. Add to the solution 20 c.c. of dilute (10 per cent) iron-free sulphuric acid, warm slightly, and then add 0.1 N (approximate) potassium permanganate solution to oxidize the ferrous salt completely. Dilute with distilled water to one liter exactly. Each cubic centimeter will contain 0.1 mg. of iron for use as a regular standard. To make weaker standards dilute this standard solution accordingly.

PROCEDURE

"Transfer accurately with an Ostwald pipette 0.5 c.c. of blood into a 50 c.c. volumetric flask and introduce 2 c.c. of iron-free concentrated sulphuric acid. Whirl the flask to agitate the mixture for one or two minutes. Add 2 c.c. of saturated potassium persulphate solution and shake. Dilute to about 25 c.c. with distilled water and add 2 c.c. of 10 per cent sodium tungstate solution. Mix. Cool to room temperature under the tap and then dilute to volume with distilled water. Stopper the flask and invert two or three times to effect thorough mixing. Filter through a dry filter paper into a clean, dry receiving vessel. Pipette exactly 20 c.c. of the clear filtrate into a large test tube graduated at 20 and 25 c.c.

"Measure into another similar test tube exactly 1 c.c. of the standard iron solution containing 0.1 mg. of Fe per c.c. Add with a graduated 1 c.c. pipette 0.8 c.c. of iron-free concentrated sulphuric acid and dilute to the 20 c.c. mark with distilled water. Cool to room temperature under the tap. Now add to both the unknown and standard 1 c.c. of saturated potassium persulphate and 4 c.c. of 3 N potassium sulphocyanate solution. Insert a clean rubber stopper, mix, and compare in a Duboseq colorimeter.

"Calculation.—As the 20 c.c. of filtrate taken represent 0.2 c.c. of the original blood, and the quantity of standard solution used contains 0.1 mg. of Fe, if the reading is made with the standard set at 20 mm., then 20 divided by the reading (*r*) of the unknown and multiplied by 50 will give the number of mg. of Fe in 10 c.c. of the blood examined. To obtain the percentage of hemoglobin, divide this number by 3.35, since hemoglobin contains 0.335 per cent of iron.

$$\frac{20}{R} \times 50 = \text{mg. of iron per hundred cubic centimeters of blood.}$$

$$\frac{20 \times 50}{R \times 3.35} = \text{percentage of hemoglobin in blood.}"$$

In some of the recent articles on blood iron the results are expressed as iron in milligrams per hundred cubic centimeters rather than as hemoglobin. Murphy, Howard, and Lynch³ have described an "iron index" in which the relation of the iron in milligrams to the red cell count in millions is calculated. Since, as I have indicated above, for every practical purpose, all the iron present is in the form of hemoglobin, I can see no reason for recording the results in terms of iron rather than of hemoglobin. Likewise, an "iron index" is the same as a color index since the relation of the iron to the cell count is again only another way of expressing the relation of the hemoglobin to the cell count.

Reich and Tiedemann¹² have suggested an "iron-volume index" which expresses the relation of the iron to the mass of packed red corpuscles. Since here again, the iron is really a measure of the hemoglobin, this is really a saturation index and serves only to confuse the issue by multiplying the various indices.

CONCLUSIONS

The iron content method is a simple and accurate method for determining the amount of hemoglobin in the blood, and the results check closely with those of the oxygen capacity method.

The iron method for the determination of hemoglobin deserves wider use in clinical laboratories for the checking of hemoglobinometers and other purposes.

For every practical purpose all the iron present in the blood is in the form of hemoglobin, so the results should be calculated as hemoglobin rather than as "blood iron."

The "iron index" is only another way of expressing the *color* index, and the "iron volume index" another way of expressing the *saturation* index.

OBSERVATIONS UPON THE LIPOKRIT METHOD FOR THE DETERMINATION OF THE LIPOID CONTENT OF BLOOD*

LOUIS G. HERRMANN, M.D., AZEL AMES, M.D., AND ROBERT J. TAPKE, M.D.,
CINCINNATI, OHIO

DURING the course of our work upon the experimental production of pulmonary fat embolism,¹ it was found that the tolerance for fat injected intravenously appeared to vary with the animal's nutrition and diet. Therefore it became necessary to control these experiments by determining the lipid content of the blood before and after the injection of fat. Accepted methods for the determination of blood lipoids, such as the Bang-Bloor chromate titration method or the gasometric method of Backlin, seemed unnecessarily detailed and laborious since we were primarily interested in relative variations of the total lipid content rather than exact quantitation of the individual lipid constituents. Our search for a simple procedure disclosed the Hemolipokrit method recently devised by Rückert² of Marburg, Germany. With a few modifications, this simple, volumetric micromethod has proved to be ideally suited to our needs, and we feel that it is of such potential value in investigative work upon "fats" that a detailed report of our experience with the method should be placed on record.

Throughout this report the term *lipoid* is used in accordance with the terminology employed by Peters and Van Slyke³ to denote the fats and fatlike substances in general, while the conjugated lipoids, such as the phosphatids and cerebrosides, are designated by the term *lipides*.

The principle of the Lipokrit method is essentially that of the Babcock method for determining the fat content of milk and cream. The proteins of the blood are changed from the colloidal state to one of molecular dissociation by means of sulphuric acid, permitting complete liberation of the lipoids by hydrolysis and centrifugation. Rückert found the optimum concentration of sulphuric acid for freeing lipoids from blood serum to be 70 per cent by weight when used in the proportion of five parts by volume of acid to one part of serum. He also devised the hemolipokrit pipette which made it possible to measure accurately the minute volume of lipoids derived from small amounts of blood (Fig. 1). The addition of a small amount of amyl alcohol to the sulphuric acid accelerates the separation of the fat droplets and facilitates their coalescence into a measurable column.

In testing the accuracy of this method, Rückert employed aqueous emulsions of the various lipoids and recovered them from the sulphuric acid, amyl alcohol mixture with an average error of only 0.004 gm. per cent. He found that

*From the Department of Surgery, College of Medicine of the University of Cincinnati and the Kuhn Memorial Laboratory, Cincinnati General Hospital.
Received for publication, March 15, 1933.

neutral fats, fatty acids, cholesterol, and cholesterin esters separated immediately upon centrifugation, while phosphatids, such as lecithin, required an eleven-hour period of hydrolysis for complete liberation of their fatty acids. Mixed aqueous emulsions of equal parts of triolein and lecithin were found to yield an increasing volume of fat and fatty acids with hourly centrifugations until a maximum constant level was reached at the end of eleven hours (Fig. 2). The

M. O. Maue 932

Fig. 1.—Sketch of the lipokrit pipette and clamp (after Rückert).

difference between the initial and final readings, therefore, represented the fatty acids derived from lecithin.

By applying the foregoing observations to the examination of blood serum, Rückert was able to establish a simple lipid partition by which the neutral fats, free fatty acids, cholesterol and cholesterin esters were obtained immediately upon centrifugation in the first fraction, while the various lipides were represented by their fatty acids in the second fraction obtained after eleven to twenty-hour hours of hydrolysis. In order to compute the volume of lipides

from their fatty acids in the second fraction, it was necessary to multiply the value for this fraction by the arbitrary factor 1.1964 obtained by assuming that lecithin, which bears a volumetric relationship of $\frac{739.4}{618}$ or 1.1964 to its fatty acid constituents, is the only important lipide of blood serum. The *total lipoid content* of a specimen of serum was then determined by adding the observed volumes-percentage of lipoids obtained in the first fraction to the computed volumes-percentage of lipides in the second fraction. Further differentiation of the lipoid partition may ultimately be possible. In serum of known high cholesterol content we have been able to demonstrate, with the polarizing microscope, a definite anisotropic layer at the base of the fat column in the lipokrit stem, but so far we have not succeeded in making consistent measurements of this layer.

At present there is no extensive work on the comparison of the results of the lipokrit method with those of other methods. Rückert,² and Leppien⁴ have made parallel volumetric and gravimetric determinations of the total lipoid content of serum. In these studies the results obtained by the volumetric method were converted from milliliters-percentage (ml.%) to grams-percentage (gm.%) by (A) applying an arbitrary specific gravity factor (obtained by assuming, as do Bloor⁵ and Backlin,⁶ that the mixture consists of two parts of fat to one of cholesterol) to the value for the mixed lipoids of the first fraction, and (B) by dividing the value of the lipides of the second fraction by the specific gravity of lecithin. The gravimetric values were obtained by extracting the lipoids with alcohol, ether, and petroleum ether and evaporating the filtrate to constant weight. The eight pairs of parallel determinations made by Rückert showed an average difference between volumetric and gravimetric results of 0.011 gm. per cent, with discrepancies ranging from 0.001 gm. per cent to 0.036 gm. per cent. In all but two, the volumetric value was the higher. In a similar series reported by Leppien the differences ranged from 0.003 gm. per cent to 0.066 gm. per cent, with an average discrepancy of 0.029 gm. per cent. All but three of these pairs showed a higher gravimetric value.

METHOD

*I. Apparatus.**—In devising the hemolipokrit pipette Rückert combined the essential features of the hematocrit tube, the erythrocytometer pipette and the Babcock bottle, adding a small inlet bulb one-fifth the volume of the mixing chamber, for measuring the proper proportion of serum. The serum bulb, the mixing chamber, and the graduated portion of the capillary stem bear a volumetric relationship to one another of 25:125:1. Accurate measurement of the sample of serum is facilitated by the addition of an "automatic" capillary tip which projects into the mixing chamber from the serum bulb (Fig. 1). The capillary stem is so calibrated that each of its 100 divisions represents 0.04 per cent of the capacity of the inlet or serum bulb. The actual volume of this bulb will vary slightly in different pipettes but the average capacity is 0.15 ml.

The hemolipokrit clamp is a great improvement over the ordinary hematocrit clip. The pipette can be held tightly enough in this clamp to permit violent shaking and high-speed

*The lipokrit pipettes are manufactured by Arno Hask, Jena, Germany. They are obtainable in the United States from the Cincinnati Scientific Company, 210 East Second Street, Cincinnati, O.

centrifugation without leakage. The difference in weight between the various pipettes and clamps is negligible thus eliminating the necessity for balancing before centrifugation.

II. Reagents.—(a) *Sulphuric Acid*: This reagent should be an aqueous solution of sulphuric acid, 70 per cent by weight with a specific gravity $\frac{20^{\circ} \text{ C.}}{4^{\circ} \text{ C.}}$ of 1.6105. Rückert found that more concentrated solutions oxidize the lipoids to a certain extent, while more dilute solutions are incapable of completely hydrolyzing the coagulated protein. We have confirmed these observations and, in addition, have found that a solution of sulphuric acid of greater specific gravity will give fictitiously high fat readings (detected by control tests with physiologic salt solution) by causing amyl alcohol to separate from the mixture. Since sulphuric acid (c. p.) varies somewhat in concentration, we have found it necessary to determine its specific gravity by means of a Westphal balance prior to making the calculations. It is also advisable to check the specific gravity of the solution which has been prepared to detect any possible error.

Fig. 2.—Sketch showing the time hydrolysis curve for aqueous emulsions of various lipoids (after Rückert).

(b) *Amyl Alcohol*: Chemically pure iso-amylie alcohol with a boiling point of 128° to 130° C. , and a specific gravity $\left(\frac{15^{\circ} \text{ C.}}{4^{\circ} \text{ C.}}\right)$ of 0.850 has been found more satisfactory for this method than the fusel oil ordinarily employed in milk analysis.

(c) *Contrast Stains*: In order to facilitate measurement of the lipoid column in the capillary stem of the lipokrit, Rückert stained the sulphuric acid with methylene blue and made the amyl alcohol a vehicle for a spirit soluble anilin yellow dye which is taken up by the fatty acid radicle. The clear, colorless fluid column in which the fatty layer is distinguishable only by the light reflex of the interface, is differentiated by this means into two sharply contrasting components—an opaque dark blue green column rising out of the mixing chamber and a supernatant pale yellow lipoid layer. The optimum concentration of these dyes in their respective solvents was found to be as follows: methylene blue (med-icinal) 0.08 gm. per 100 ml. of the 70 per cent sulphuric acid solution, and anilin yellow

0.15 gm. per 100 ml. of amyl alcohol. We have found that a saturated solution of secharlach R in amyl alcohol is a much more effective stain for the lipid layer than any anilin yellow dye which we have been able to obtain in this country. The bright red color imparted to the lipoids affords a much more striking contrast with the blue green color in the stem of the lipokrit pipette.

III. Technic.—(a) *Preparation of the Blood Sample:* The blood is taken from an artery or vein with small glass syringes which have been cleaned in sulphuric acid—potassium dichromate solution and dried with alcohol and ether, using rustless steel needles rendered fat-free by acetone and sterilized in the autoclave. In order to prevent hemolysis the needles and syringes must be absolutely dry. Two milliliters of blood is ample for duplicate de-

Fig. 3.—Photograph of the accessory apparatus. *a*, Capillary pipette for separating the serum. *b*, Automatic burette bottle for sulphuric acid, methylene blue solution. *c*, Automatic microburette bottle for amyl alcohol secharlach R solution. *d*, Glass stoppered weighing bottles for mixing the special reagent. *e*, Motor-driven shaking machine for the lipokrit pipettes. *f*, Special duralumin centrifuge head. *g*, Heat insulated slit lamp with magnifying glass and microburner attached.

terminations. The specimens are transferred to chemically clean, fat-free culture tubes 5 inches in length, and then centrifuged as soon as the clot has formed. We have found that centrifugation at approximately 1900 r.p.m. for five minutes in a No. 1C International centrifuge with head No. 233 fitted with the usual small cups gives the maximum yield of serum with a minimum demulsification of the fats. The supernatant serum is then transferred to another tube by means of a special large capillary pipette drawn from a 6-inch hard glass culture tube and fitted with an "asepto" rubber bulb (Fig. 3, *a*).

(b) *Preparation of the Reagent Mixture:* The sulphuric acid-amyl alcohol mixture is prepared by adding 1 volume of the amyl alcohol-secharlach R solution to 12.5 volumes of the sulphuric acid-methylene blue solution. Rückert found that when smaller proportions of alcohol are used the fat droplets tend to remain discrete and fail to coalesce properly upon

centrifugation, while larger proportions of amyl alcohol interfere with the hydrolysis of the proteins. Furthermore, the mixture should be *freshly* prepared for each set of determinations because amylene is formed on standing and will rise with the lipoids upon centrifugation and give fictitiously high fat readings. We have confirmed these findings to the extent of observing somewhat higher readings with the use of sulphuric acid-amyl alcohol mixtures which were twenty-four to seventy-two hours old. We have found it most convenient to keep these solutions in "all automatic" burette bottles (Fig. 3, *b* and *c*), using a microburette for the amyl alcohol, and protecting the sulphuric acid solution from atmospheric moisture by "trapping" the vents with calcium chloride tubes and stoppering them when not in use. With this equipment small amounts of reagents may be measured out and freshly mixed for each set of determinations with a minimum of waste and exposure, and a maximum of speed and accuracy. Approximately 0.75 ml. of the mixture is needed for each determination, consequently a series of 12 determinations would require 10 ml. of the sulphuric acid-methylene blue solution and 0.8 ml. of the amyl alcohol-scharlach R solution. These fluids should be thoroughly mixed by shaking vigorously for five minutes and warming to about 50° C. For

Fig. 4.—Alimentary lipemia curve of a normal adult.

this purpose narrow 4-inch glass-stoppered weighing bottles (Fig. 3, *d*) have proved most convenient. After mixing, the reagent should be allowed to stand for about twenty minutes or until it has cooled to room temperature and is free from bubbles. We have found that the premature use of this mixture causes a collection of foam in the lipokrit stem which interferes with the coalescence of the fat droplets. The reagent should, therefore, be prepared about thirty minutes before it is to be used.

(c) *Filling the Pipettes:* The serum should be agitated by gentle rotation of the tube to insure homogeneous distribution of the lipoids which sometimes come to the top of the serum during centrifugation. Violent shaking should be avoided because of the inconvenience of the resulting bubbles. The lipokrit pipette is then introduced into the tube and the serum is slowly drawn up into the measuring bulb until the automatic capillary tip is filled. The pipette is withdrawn, held horizontally while the end is wiped dry and then dipped into the reagent mixture. This is sucked up *quickly* through the inlet bulb to prevent coagulation of the serum in the automatic tip, and then drawn *very slowly* into the mixing chamber. During this process the pipette should be held vertically and twirled rapidly to and fro between the thumb and forefinger as the fluid rises. At least one minute should be consumed in filling this chamber, for if the process is hurried, dissociation of the coagulated protein will be sufficiently delayed to retard the liberation of the lipoids and lead to low readings

after the initial centrifugation. The reagent should be allowed to rise but halfway up the capillary stem, and when it has been adjusted at the 50 mark, the pipette should be withdrawn to the horizontal position, wiped dry, and fitted tightly into the lipokrit clamp. The apparatus is then shaken vigorously in a motor-driven device (Fig. 3, e) for five minutes. If the time intervals for filling and shaking have been properly observed, the fluid column will be found to have contracted with cooling to the level of the 10 or 15 mark at the base of the capillary stem, and this incompletely hydrolyzed portion may be allowed to run back into the mixing chamber without fear of losing any lipoid material at the inlet. Filling of the pipette is then completed by again drawing up reagent until the column reaches the 100 mark at the top of the stem. The objections to filling the pipette in one stage are, first, incomplete hydrolysis of the material in the stem, and second, contraction of the fluid column into the mixing chamber upon cooling. If the pipettes are filled properly in two stages, the fatty layer will always be found within the limits of the graduated portion of the capillary stem.

(d) *Centrifugation*: In his original publication of this method, Rückert specified centrifugation at a speed of 2,000 r.p.m. for ten minutes, but later in a personal communication to us he stated that he had found it necessary to increase the speed of centrifugation to 4,000

Fig. 5.—Alimentary lipemia curve of an obese adult.

r.p.m. in order to obtain the most constant and accurate results. We have found that the speed of centrifugation (the radius remaining constant) must be governed by the time hydrolysis curve of the lipides in relation to the total (elapsed) time necessary for filling, shaking, and centrifuging a given number of pipettes. By repeated determinations at various speeds on the same specimen of serum, with centrifugation for periods of five minutes at five-minute intervals, we have learned that the lipoids of the first fraction are usually liberated completely in from ten to thirty minutes after filling the pipettes, depending upon the degree of centrifugal force applied. We have also found that the hydrolysis of the lipides commences after thirty minutes have elapsed regardless of the speed and duration of centrifugation. It seems to be essential, therefore, that readings for the first fraction be completed within thirty minutes after filling the pipettes. If twenty minutes were required to fill and shake 4 pipettes then they should be centrifuged with sufficient force to liberate the entire first fraction in the remaining ten minutes, while if only 2 determinations were to be made, requiring but ten minutes for filling and shaking, there would be twenty minutes left for centrifugation and the separation could be accomplished at a slower speed with a centrifugal force which would be inadequate for a shorter interval. The "sedimentation-time" for lipid emulsions may be said to be approximately inversely proportional to the relative centrifugal force

(R. C. F.). Example: Using an International centrifuge No. 1C with head No. 233 and 2 small carriers (rotating radius of the center of gravity of the fluid mass being 15 cm.) at the maximum obtainable speed of 1,900 r.p.m., we were able to apply a centrifugal force of only 589,235 dynes/gm. (R. C. F. 601 gm./gm.), and complete liberation of the first lipid fraction required a twenty-minute period of centrifugation; while with the same centrifuge but a special duralumin head (radius 11.25 cm.) designed to reduce "windage," a speed of 3,500 r.p.m. was obtained, and the resulting centrifugal force of 1,502,156 dynes/gm. (R. C. F. 1,533 gm./gm.) was sufficient to separate these lipoids in about eight minutes. Theoretically this work could be accomplished in approximately one minute by an R. C. F. of 12,000 gm./gm. From these observations the following proportion may be stated, by means of which it is possible to estimate the *number of minutes of centrifugation* (T) required for any given combination of *speed* (N in r.p.m.) and *radius* (R in cm.), i.e.,

$$T : 1 :: 12,000 : 0.0000111N^2R$$

$$T = \frac{1,081}{\left(\frac{N}{1,000}\right)^2 R}$$

If T *plus* the time required for filling and shaking the desired number of pipettes is found to be thirty minutes or more, a greater centrifugal force will be needed. Although most of the determinations which we present in Tables I and II were made with an R. C. F. of 600 gm./gm. for fifteen minutes and a total (elapsed) time of twenty minutes for separating the first fraction, we are now convinced that in order to obtain comparable and uniform results *the initial centrifugation should be made consistently with an R. C. F. of 1,200 gm./gm., for a period of ten minutes and that the total elapsed time (from filling to reading) should be uniformly limited to twenty-five minutes.* The specified centrifugal force may be obtained with the following equipment:

MAKE OF CENTRIFUGE	MODEL	TYPE OF HEAD	SPEED
International	1C	Special (Fig. 3, f)	3,000 r.p.m.
International	1SB	Nos. 210; 220; 225	2,900 r.p.m.
International	2	Nos. 251; 240; 241	2,700 r.p.m.

(e) *The First Fraction: Readings.* After centrifugation the fluid column will usually be found to have contracted to the 70 or 80 mark on the lipokrit stem, and the coalesced, liberated lipoids, stained a bright scarlet, will be layered over the dark blue green reagent mixture at about this level. The length of the lipid column should be read promptly with the aid of a magnifying glass and a bright light. Because of the thermometer-like behavior of the sulphuric acid, a cool source of light is desirable, and we have found that readings are facilitated by the use of a heat-insulated slit-lamp (Fig. 3, g). Frequently a portion of the lipoids solidifies on cooling, and in order to obtain a clear-cut interface it is necessary to warm the portion of the lipokrit stem occupied by the fatty layer in the flame of a micro-burner. There is no appreciable expansion of the column of fat on heating. In cold weather it is advisable to do this routinely as quickly as possible, because slight warming of the bulbs from contact with the hands or lamp will make the fluid rise and leave solidified lipid particles behind thereby necessitating recentrifugation. Each division of the lipokrit scale is equivalent to 0.04 per cent of the volume of the serum taken into the pipette. It is possible to read accurately to one-tenth of one division. For example, a fatty layer occupying 9.6 divisions would represent a content of 0.384 ml. of neutral fat, free fatty acids, cholesterol and cholesterol esters per 100 ml. of serum. In view of the differences in specific gravity and variations in the relative proportions of these lipoids, we prefer to report the value for the first fraction in terms of the observed relative volume rather than attempt to transpose it into gravimetric units.

(f) *The Second Fraction: Time hydrolysis curve of the lipides.* After taking the initial readings, Rückert allowed the pipettes to stand for twenty-four hours in an incubator at 37° C., in order to obtain complete hydrolysis of the lipides. We have learned, however, from

parallel determinations at 37° C., and at room temperature (22° C. to 27° C.), that the rate and completeness of hydrolysis are not influenced appreciably by temperature within these limits. We have also observed that somewhat lower readings are frequently obtained after incubation at 37° C. due to the loss of small amounts of lipoid material which adhere to the glass above the capillary bore when the fatty layer is carried to the top of the stem on

warming. Consequently, we prefer to carry out this process at room temperature. Furthermore, we believe that there is not sufficient difference between twelve-hour and twenty-four-hour readings to justify depriving the laboratory of the use of the lipokrit pipettes for more than twelve hours. Evidence for this opinion is presented in Table I of 10 determinations in triplicate (Table I). After the twelve-hour period of hydrolysis, the fatty acids derived from lipides are added to the lipoids of the first fraction by a second period of centrifugation which should be identical with the first.

IV. Calculations.—The value for the reading obtained after the twelve-hour period of hydrolysis does not represent the total lipid content of the

the first fraction. These calculations are greatly facilitated by the use of Table II prepared by Rückert, in which the ml. per cent of lipides (phosphatids), computed from their fatty acid components, is given for any number of divisions of the lipokrit scale from 1 to 59.

V. *Results*.—Fig. 6 shows the volume of lipoids in the blood serum, after fourteen hours of fasting, as determined by the lipokrit method in a series of 37 normal patients.

Since only a small quantity of blood is needed for each set of determinations made by this method, the rate and degree of absorption of fat from the alimentary canal can be studied easily and without injury to the patient. Several normal adults volunteered for such studies. All of these patients were given the same diet of known composition. The lipoids of the blood were determined at hourly intervals for twenty-four hours. The results of two of these series of determinations are shown in the accompanying curves (Figs. 4 and 5). A more detailed report of similar studies will be presented at some later time.

SUMMARY

The lipokrit method is a simple volumetric micromethod for the determination of the lipoid content of blood serum.

Slight alterations of the original method of Rückert with certain refinements of technic have made it possible for us to obtain consistently uniform results.

The lipoid content of the blood serum, after fasting for about fourteen hours, appears to be fairly constant regardless of the age or sex of the individual.

Two curves showing the typical increase in the lipoids of the blood which occurs several hours after each meal are presented.

NOTE: The authors wish to express their appreciation to Dr. Glenn E. Cullen, Director of Laboratories of the Children's Hospital Research Foundation, for his kind cooperation and many valuable suggestions during the course of this work.

THE MODIFIED GRAM STAIN OF MUCH*

OTTO S. KRETSCHMER, A.M., M.D., DENVER, COLO.

B. MÖLLERS, in the *Handbuch der pathogenen Mikroorganismen* (1930), states that "in the various forms of human tuberculosis one finds only the acid-fast form of the tubercle bacillus, or one attributes only to this form a diagnostic value." In a previous paper¹ by me it was seen that the classical tubercle bacillus has no genuine Gram property as long as the organism is acid-fast; moreover, that it cannot have this property because of the presence of the acid-fast lipoids. It was found further that when the tubercle bacillus was completely deprived of its acid-fast material, it became gram-negative. H. Much,² however, claimed to have found, with the aid of a modified Gram staining technic, a pathogenic granular nonacid-fast form of the tuberculosis virus, a form hitherto unknown. According to his findings this organism, when stained by his method, is found to consist either of a very short, beaded fragmented rod or of isolated granules, or heaps of granules, all of which are nonacid-fast and gram-positive.

When one studies the Gram technic of Much, it will be seen that the latter employs two carbol dyes such as are used in acid-fast staining, viz., carbol-fuchsin 3 parts, carbol methyl violet 1 part. Moreover, Much's technic requires prolonged cold staining up to forty-eight hours. In order to give the method a semblance of the Gram stain, the organisms are then exposed to hot iodine solution for five minutes. This is followed successively with 5 per cent nitric acid for one minute, 3 per cent hydrochloric acid for ten seconds, and finally with equal parts of 95 per cent alcohol and acetone. These latter are acid alcohol acetone decolorizers that are even more powerful in their action than those applied in the classical Ziehl-Neelsen acid-fast method, in which only 3 per cent hydrochloric acid in 70 per cent alcohol is employed. Consequently, any microorganisms retaining the Much dyes after being treated with these decolorizers must be considered not merely alcohol-fast as required of gram-positive organisms but acid-fast as well. Hence, this led me to conclude that the so-called modified Gram stain of Much is really an acid-fast staining technic, and that the Much granules are in reality acid-fast bodies. In order to observe the action of Much's staining method on acid-fast tubercle bacilli, some experimental work was carried out in which this staining technic was analyzed into its separate procedures.

Experiment 1.—*Purpose:* To determine the action of the Much's modified Gram staining technic on untreated acid-fast tubercle bacilli. Exposure time, forty-eight hours. The tubercle bacilli stained an intense purplish blue especially the granules which stand out like cocci either in rows or in clusters. One could scarcely note any difference between these and Much's granules as found in the pus from cold abscesses. None of the bacilli stained red, the purplish blue color predominated (Fig. 1).

*Received for publication, January 7, 1933.

Experiment 2.—Purpose: To determine the effect upon color retention of untreated tubercle bacilli stained with aniline gentian-violet as employed in the standard Gram stain, of the decolorizing agents employed in the Much staining technic.

A. Tubercle bacilli were stained on slides at room temperature for one minute with aniline gentian-violet. Gram's iodine was applied for five minutes hot as in Much's technic. Decolorization with 5 per cent nitric acid for one minute, 3 per cent hydrochloric acid for ten seconds, acetone alcohol until color ceases to come off.

Results: Organisms were well stained. They retained their color after use of Much's decolorizers.

B. Tubercle bacilli were treated as under A, with one-minute exposure to cold Gram's iodine solution.

Result: Organisms were equally well stained as in A.

C. Tubercle bacilli were treated as under A, but without iodine.

Fig. 1.—Tubercle bacilli of the beaded type which have been stained according to Much's technic, resembling Much's "granules." Note intergranular bridges, one of the requisites of true "Much granules."

Result: The organisms retained stain in spite of lack of application of iodine when the Much acid acetone alcohol decolorizing solutions were employed.

Experiment 3.—In this experiment the Much modified Gram stain was analyzed by staining untreated intact pulverized living tubercle bacilli with the separate components of this technic in order to ascertain whether all the steps of the Much technic tend to increase its efficiency in tinctorially demonstrating the tubercle bacillus. The results of the experiment are recorded in Table I.

Comment on Experiment 3: It will be seen in B of Table I that when the entire system of decolorizers employed in Much's staining technic is employed, the intensity and the quality of red of the carbolfuchsin are greatly altered so that the tubercle bacilli are scarcely recognizable. On the other hand as seen in A of the table the methyl violet is but little altered in these respects by the same decolorizers.

From the above staining analysis, by the process of elimination it appears that the principle offender in causing alteration of the color quality and intensity of the carbolfuchsin is the nitric acid. This acid changed the brilliant red of the carbolfuchsin either to a pale lavender or entirely decolorized the tubercle bacillus of this stain whether iodine was used or not. The action of nitric acid on methyl violet, however, is not so marked. Hence, the carbolfuchsin adds practically nothing to the end-staining result since the nitric acid nearly decolorizes this stain when applied to the tubercle bacillus in the course of the Much technic.

Moreover, it will be seen that the tubercle bacillus stains as well and better without, as with, iodine. When iodine was applied after the carbol methyl violet, the former produced an annoying granular precipitate which obscured the tubercle bacilli and simulated the granules of the latter. It causes a change in color quality and staining intensity of the carbolfuchsin.

It is consequently evident that in employing the Much staining technic

TABLE I

TUBERCLE BACILLI STAINED WITH:				
A. CARBOL METHYL VIOLET			B. CARBOLFUCHSIN	
DECOLORIZER	WITH IODINE	WITHOUT IODINE	WITH IODINE	WITHOUT IODINE
1. HNO ₃ , HCl, Acetone alcohol	Intensely stained	Intensely stained	Practically not stained	Poorly stained. Nearly decolorized
2. HNO ₃ , Acetone alcohol	Well stained	More intensely stained than with iodine	Practically not stained	Practically not stained
3. HNO ₃ , HCl	Stain precipitated in small granules, obscuring tubercle bacilli	No precipitate. Bacilli well stained	Very poorly stained, a lavender color	Very poorly stained, a lavender color
4. HNO ₃	So much granular precipitate as to obscure bacilli	No precipitate. Bacilli well stained	None bright red; some pink	Not bright red. Lavender. Most organisms not stained or poorly so
5. HCl, Acetone alcohol	No precipitate. Not as intensely stained as (1) above	No precipitate. Bacilli well stained	Practically not stained	Well stained. Bright red
6. HCl	Much granular precipitate obscuring bacilli	No precipitate. Bacilli well stained	Not distinctly stained	Stained bright red
7. Acetone alcohol	No precipitate. Bacilli well stained	Slight granular precipitate. Bacilli not obscured by precipitate. Latter well stained	None bright red. Poorly stained	Well stained, red
8. Acetone	Granular precipitate. Bacilli well stained	No precipitate. Bacilli well stained	Lavender tubercle bacilli. None red. Faintly stained	Stained red
9. Alcohol	Much granular precipitate. Bacilli well stained	No precipitate. Bacilli well stained	No stained tubercle bacilli at all	Well stained, red

we are not dealing even with a modified Gram stain but with an acid-fast stain for the following reasons:

- The component dyes of the Much stain are typical acid-fast stains.
- The Gram's iodine adds nothing to the value of the Much staining technic since typical tubercle bacilli will stain as well without iodine as with it, in fact, somewhat better without it (see Table I).
- Tubercle bacilli stained with Much's stain will retain the latter (whether treated with iodine or not) not only after decolorization with alco-

hol, as is to be expected of a gram-positive organism, but also after decolorization with nitric and hydrochloric acids, and acetone alcohol. Hence the stain is an alcohol acid-fast stain and not a Gram stain.

d. In these experiments the tubercle bacillus has been used to determine the acid-fast property of the Much stain, since this organism is generally considered the most acid-fast one of that group. If, then, it be correct, as asserted by Much, that the so-called Much "granules" are nonacid-fast gram-positive bodies representing an atypical form of the tuberculosis virus, he should have employed a method of staining other than that devised by him, since his is an acid-fast stain and the bodies stained therewith are, consequently, acid-fast "granules" (they are not always granules, but frequently show connecting intergranular bridges or bacillary structure), resembling, in reality, the granular forms of the typical tubercle bacillus.³

Experiment 4.—The purpose of this experiment was to ascertain whether the method of concentrating tubercle bacilli affects unfavorably the staining of these organisms by the Much technic. In this method of concentrating tubercle bacilli (and "Much granules") from sputum and pus from cold abscesses, strong alkalis (0.6 per cent sodium carbonate and antiformin which contains sodium hydroxide) are applied for forty-eight hours in order to liquefy the tenacious sputum. The organisms so liberated are then concentrated by centrifugation and applied in the alkaline sediment to slides, dried and stained.

With this in view pulverized intact acid-fast tubercle bacilli were treated with the above concentrating solutions, centrifuged after forty-eight hours and half of them applied to slides without being washed free from alkalis; the other half was repeatedly washed in distilled water until neutral to litmus and then applied to slides and dried. The unwashed bacilli were then stained as follows:

1. With Much's carbofuchsin and carbol methyl violet for forty-eight hours, hot Gram's iodine five minutes, decolorized with nitric acid, hydrochloric acid, acetone alcohol.

Results: The tubercle bacilli were stained indistinctly a slate blue color.

2. With carbofuchsin forty-eight hours, hot Gram's iodine five minutes, decolorized with nitric acid, hydrochloric acid, acetone alcohol.

Result: Tubercle bacilli were stained, but not distinctly, a pale lavender instead of a bright red.

3. With cold carbol methyl violet forty-eight hours, hot Gram's iodine five minutes, decolorized with nitric and hydrochloric acids and acetone alcohol.

Result: Tubercle bacilli stained a dark gray-blue, with the granules well stained, the intergranular substance often was not stained; if stained at all, the latter took the dye faintly as a rule. These tubercle bacilli appear very much like the typical Much "granules."

4. With carbofuchsin, hot, five minutes; decolorized with acid-alcohol, counterstained with methylene blue.

Result: The tubercle bacilli were stained more distinctly than under (2) but not a brilliant red.

Comment: From the first part of Experiment 4 it will be seen that the alkalis employed to concentrate the tubercle bacilli in sputum or pus from cold abscesses, previous to the application of the Much "granule" staining technic, are distinctly detrimental to the staining of tubercle bacilli with Much's carbofuchsin and carbol gentian violet both as to intensity and color quality. The tubercle bacilli treated with these alkalis do not stain typically bright red with carbofuchsin. Only carbol methyl violet, after application of these alkalis, colors the tubercle bacillus with moderate intensity.

The washed bacilli were stained as follows:

1. With hot carbolfuchsin five minutes (as in 4 above), hot iodine solution five minutes and Ziehl-Neelsen acid alcohol decolorizer.

Result: The tubercle bacilli were stained reddish, but not a bright red.

2. With the same as in (1) without the iodine.

Result: These tubercle bacilli stained a brilliant red.

Comment: The second part of Experiment 4 demonstrates the following:

a. That if the alkalis used in concentrating tubercle bacilli are removed by washing from the material to be stained, they will not interfere with the staining property of the carbolfuchsin of the Ziehl-Neelsen stain, but if not properly removed they may render the organisms unrecognizable or difficult to find due to poor staining. This may account for some of the failures to detect tubercle bacilli when the concentration method is employed. This method would not, however, interfere seriously with the discovery of the organisms if stained with the intensely blue staining carbol methyl violet of the Much method. This may consequently account for the greater efficiency of the Much staining method in detecting rare tubercle bacilli after application of the above alkaline concentration method.

b. The addition of iodine in the Much technic alters to a considerable extent the bright red color of the carbolfuchsin but not greatly the color quality of the carbol methyl violet.

Experiment 6.—A freshly isolated culture of virulent streptococci was stained according to Much's technic in order to ascertain the effect of this stain upon a typical Gram positive nonacid-fast organism.

Result: Streptococci were completely decolorized by the acid acetone alcohol decolorizers of the Much technic. Only occasional faint outlines of organisms were visible.

Comment: The Much stain is not a Gram stain but acts as an acid-fast stain when applied to known gram-positive organisms.

DISCUSSION

Much² maintained that he had discovered a new form of nonacid-fast tuberculosis virus which he claims to have demonstrated by a staining technic devised by him and designated a modified Gram stain. This virus so stained appeared either as purple isolated granules or as heaps of granules, or as beaded, bandlike structures. Unless these granules were connected by a faint bluish or reddish band, it was said, they should not be considered to be true Much granules.³ This claim of Much to the discovery of an atypical tuberculosis virus has been supported by some and called into question by many, so that B. Möllers⁴ in the *Handbuch der pathogenen Mikroorganismen* states recently that the question is still unsettled. Much, however, in his autobiography recently states that his discovery of the virus now is an established fact of science. Although this assertion may well be questioned, the true nature of the "granules" has not been gone into in this paper. In the work here presented, merely the staining method of Much has been called into question.

First, it is claimed by Much that his staining method is a modified Gram staining technic. The work recorded in this article has shown that this claim of Much is incorrect. That first of all his staining technic is not a modified

Gram stain; and second, that it is an acid-fast and not a nonacid-fast stain. In order to prove the former of these contentions gram-positive organisms were employed. These were shown by Much's method to lose their original stains (carbol genitan violet and carbolfuchsin) upon application of his decolorizers following application of hot Gram's iodine solution. According to Much's method then, these gram-positive organisms would have to be considered gram-negative. This would prove incompatible with our conceptions of a Gram stain. The evident reason for the decolorization of these gram-positive organisms is the presence in the Much decolorizers of two acids, besides alcohol and acetone. For a microorganism to be considered gram-positive it must resist alcohol decolorization after application of iodine solution. If a microorganism resists decolorization with acid, even though iodine solution has been applied, it is an acid-fast organism. Such is the case with the Much technic. It is an acid-fast technic and merely the inclusion by it of Gram's iodine solution which adds nothing to its efficacy does not make it a Gram stain. In order further to prove this assertion acid-fast tubercle bacilli were stained with the Much technic and they retained the Much stain after the application of HCl and HNO₃ decolorizers.

Moreover, it was seen in a previous article¹ that the tubercle bacillus in its acid-fast pathogenic state has no true Gram property, because it requires no iodine to enable it to retain its original stain and is not only alcohol but also acid-fast. That, consequently, its acid-fast property precluded the possibility of its possessing genuine gram-positivity. Hence the retention on part of the tubercle bacillus of the Much stain indicated not gram-positivity but acid-fastness.

Thus it will be seen from the experiments in this paper that the Much stain is not a Gram stain, but is actually a powerful acid-fast stain (carbol-fuchsin and carbol methyl violet) that is applied over a prolonged period of time (forty-eight hours), the decolorizers are two strong mineral acids (HCl and HNO₃), followed by acetone and alcohol. The iodine was found in the above experiments to be not only unnecessary but detrimental in the retention of the original stain. It was, moreover, found that when the Much staining technic was applied to a pure culture of living beaded acid-fast tubercle bacilli on slides, the latter presented the characteristics of Much "granules" (see Fig. 1). Consequently, it appears from this work that the bodies called Much granules are really acid-fast entities, and not nonacid-fast gram-positive bodies as claimed. No other known nonacid-fast organisms will remain gram-positive in the face of acid alcohol as was seen in Experiment 6.

Why, when stained with Much's carbolfuchsin carbol gentian-violet stain, do the Much bodies appear deep purplish blue and not reddish? This occurs, as seen in this work, for the following reasons:

1. The gentian-violet obscures the fuchsin due to its darker coloration.
2. The alkali of the method of concentrating tubercle bacilli in sputum and pus interferes with the bright red of the fuchsin, not only of the Much method, but also of the Ziehl-Neelsen method. This probably accounts for the fact that Much "granules" have more frequently been demonstrated than tubercle bacilli with the Ziehl-Neelsen stain in pus from cold abscesses.

3. The nitric acid changes the color quality of the fuchsin to a lavender shade but has no apparent effect on the methyl violet.

In order to demonstrate that the so-called Much "granules" are actually a tuberculosis virus apart from the standard tubercle bacillus, it will be necessary for Much or the other advocates of this staining method to employ other than an acid-fast stain to demonstrate nonacid-fast bodies. As to what the real nature of the Much "granules" may be was not a part of the above work to ascertain, but these bodies greatly resemble granular tubercle bacilli or fragments thereof (see Fig. 1).

CONCLUSIONS

1. The Much staining technic is not a true or a modified Gram stain because it employs acid decolorizers instead of only alcohol as for the classical Gram stain.

2. It is an acid-fast stain because in it carbol dyes and acid alcohol decolorizers are employed. When the most important pathogenic acid-fast micro-organism, the tubercle bacillus, is stained according to Much's technic, the latter is shown to be a strong acid-fast stain for this organism whose visibility is superior to that of tubercle bacilli stained with the Ziehl-Neelsen.

3. When the Much stain is applied to the granular form of the tubercle bacillus, the latter resembles, in fact is, indistinguishable morphologically from Much's granules. This work has not, however, endeavored to determine whether the Much "granules" are really tubercle bacilli or not.

4. If the "granular" bodies that are found in certain sputa and in pus from cold abscesses by the Much staining method are actually a different form of tuberculosis virus, one that is nonacid-fast and gram-positive, then this technic cannot be employed to demonstrate such a virus since it is an acid-fast staining procedure.

AN EVALUATION OF THREE METHODS FOR THE DEMONSTRATION OF TUBERCLE BACILLI FOR USE IN HOSPITAL ROUTINE^{*}

A SPECIAL STUDY OF SEVERAL SIMPLE CULTURE MEDIUMS

NELL HIRSCHBERG, M.A., CHICAGO, ILL.

IN RECENT years the efficacy of the culture method for the isolation and identification of the tubercle bacillus from various types of tuberculous material has received considerable notice in the literature. Corper and Uyei^{1, 2} have reviewed the work of previous authors and published reports comparing the guinea pig inoculation method with the culture method. The question of the superiority of either method is still under discussion. Recent authors, Herrmann, Hansmann, and DeCapito,^{3, 4} report superior results with guinea pig injections. At the same time, Norton, Thomas, and Broom⁵ advocate the use of the culture method on the grounds of economy as well as efficiency.

The guinea pig inoculation method has been criticized because many guinea pigs contract tuberculosis spontaneously or have internal lesions which resemble those caused by the tubercle bacillus. Howell and Schultz⁶ report an epizootic among guinea pigs due to a paratyphoid B bacillus which caused lesions closely resembling tubercles in the spleen and liver. Magath and Feldman⁷ in a recent complete review of the subject conclude that with reasonable care spontaneous tuberculous infection of guinea pigs can be avoided. Cummings⁸ has reported the incidence of spontaneous tuberculous infection in laboratory animals in Saranac, a tuberculosis center.

In the present study an attempt has been made to compare direct smear, guinea pig inoculation and culture methods for the demonstration of the tubercle bacillus in the routine specimens received in the laboratory of a large hospital. This study differs from many previous ones in that no attempt was made to obtain material from clinically tuberculous patients. In hospital laboratories, the bacteriologist is more often concerned with ruling out a possible tuberculous infection rather than confirming a clinical diagnosis of tuberculosis. In many instances the diagnosis may be obscure or deferred until laboratory reports are complete. Therefore, the time element is important and must enter into a study of methods for the demonstration of the tubercle bacillus. As Feldman and Magath report,⁹ animal inoculation remains the most satisfactory method for determining the virulence of an isolated acid-fast organism. However, if the condition of the patient indicates to the clinician the pathogenicity of the "unknown" causative organism, a quick laboratory report of an acid-fast bacillus of typical tubercle bacillus morphology and growth is of more value than a belated

^{*}From the Department of Bacteriology of the Nelson Morris Memorial Institute for Medical Research of the Michael Reese Hospital, aided by a grant from the Leon Klein Fund.
Received for publication, March 3, 1932.

report of a virulence test. In this respect the culture method supplements identification of the tubercle bacillus by direct smear.

In some instances even a prolonged search fails to demonstrate tubercle bacilli in certain specimens. In that case, other methods of demonstration must supplement direct smears. Pottenger^{10, 11} states that a search for five minutes yields 80 per cent of positive diagnoses obtainable in a fifteen-minute search; and that with careful work a longer search than fifteen minutes is not justified by the additional results. Von Huth and Lieberthal¹² state that smears were negative and cultures positive for the tubercle bacillus on 50 of 200 urines from tuberculous kidneys. They claim absolute reliability for the culture method. Corper,¹³ realizing the difficulty of the quick demonstration of tubercle bacilli by direct smear when only small numbers of the bacilli are present in a specimen, has recently devised a tissue substrate culture method to supplement identification of the organism by direct smear.

In the present study 69 specimens (Table I) were examined by direct smear, guinea pig inoculation and culture methods. Table I outlines these cases according to the clinical diagnoses. Direct smears were examined for thirty minutes. Fourteen specimens were obtained from clinically tuberculous patients. Of these, 5 specimens were positive by all three methods. In 2 cases, smears were positive and the results were not confirmed by either cultures or guinea pig injections; when examined after two months both cultures and

guinea pigs showed no evidence of tubercle bacilli. In 5 cases, demonstration of the tubercle bacillus was accomplished when both smears and guinea pig inoculations gave negative results. In one case, all three methods gave negative results, and in another case both guinea pig inoculations and culture methods yielded a positive result when direct smears had been negative. Of these specimens from clinically known tuberculosis cases, 7 were proved positive by direct smear, 6 by guinea pig inoculation and 11 by culture methods.

Fourteen specimens were obtained from clinical cases not diagnosed as tuberculosis. In addition to the negative clinical diagnosis, routine cultures showed the presence of other organisms. The 14 specimens were negative for tubercle bacilli when examined by all three methods.

Forty-one specimens were sent to the laboratory with no clinical diagnoses on the records. In four instances guinea pig inoculations and cultures gave a positive result although the direct smears were negative. In two other cases, the guinea pig injections and direct smears were negative, but tubercle bacilli were isolated by cultures. In one instance the guinea pig inoculation alone showed a positive result. In this series a total of 5 specimens gave positive results by guinea pig inoculation, 6 by culture and none by direct smear. Thirty-four specimens were negative for tubercle bacilli when tested by all three methods.

Table II summarizes these results. From these figures the inadequacy of direct smears for the demonstration of tubercle bacilli and the superiority of culture methods to the guinea pig inoculation method is obvious.

Many types of culture mediums for the cultivation of the tubercle bacillus have been devised. Most of them have a base of eggs or potatoes and are reinforced with glycerol. Corper and Uyei^{14, 15} have reported excellent results with crystal violet potato cylinder medium. The efficiency of the egg mediums of Miraglia,¹⁶ Hohn,¹⁷ Lubenau,^{18, 19} Dorset,²⁰ Sweany and Evanoff,²¹ and more recently Herrold,²² Feldman,²³ Woolley and Petrik,²⁴ has also been favorably

reported in the literature. Koch's²⁵ original serum medium has given way to synthetic mediums such as Long's.^{26, 27} A simple medium with asparagin as a source of nitrogen has been devised by Lowenstein.^{28, 29, 30} The asparagin is substituted for meat extracts which, he says, will not inhibit the growth of the tubercle bacillus. It is doubtful whether the ideal medium for the cultivation of the tubercle bacillus has yet been devised.

In routine laboratory procedure it is obviously impossible to employ a large number of mediums. In order to determine the most satisfactory ones, cultures were made on several well-known mediums using Corper's, Hohn's and Miraglia's

as controls. One specimen with a positive direct smear showed growth of tubercle bacilli in seven days on both Hohn's and Miraglia's mediums, but seventy-five days were required for growth to appear on Lubenau's egg medium. Four specimens were cultivated on Herrold's egg yolk agar. No growth was obtained on this medium or on the controls. Known cultures of tubercle bacilli grew very poorly when transferred onto Herrold's medium. In spite of careful precautions, tubes of Herrold's medium dried out early in the long period of incubation necessary for the growth of tubercle bacilli. This medium also showed a high percentage of contaminated cultures. These experiences substantiate the statement of Magath and Feldman⁵ that Herrold's reports are not complete. Woolsey,³¹ however, has found Herrold's medium an excellent means of demonstrating tubercle bacilli.

Woolley and Petrik's egg medium is rather complicated to prepare, but supports excellent growth and, therefore, may be used for stock cultures of tubercle bacilli. Of 36 specimens cultured on this medium and on the controls, two were positive on the controls and one on Woolley and Petrik's medium after twenty-five days. Nineteen of these same specimens were cultivated on 5 per cent glycerol agar, long a standard medium. The same specimens which showed growth of tubercle bacilli in twenty-five days on Woolley and Petrik's medium became positive in fifty days on the glycerol agar. Glycerol agar may be used for stock cultures of tubercle bacilli, but it dries out rapidly and often becomes contaminated.

Thirty-one specimens were cultured on Lowenstein's medium. Three of these specimens were positive on the controls, none on Lowenstein's medium. Eight blood samples were included on this series. Five of them were from patients with acute arthritis or rheumatic fever, one of them from a case of typhoid, and two from tuberculous patients. All eight specimens gave negative results on the controls as well as on Lowenstein's medium. This is contrary to Reitter and Lowenstein's³² report that a high percentage of positive growth of tubercle bacilli is obtained when blood specimens from arthritic, rheumatic and tuberculous patients are cultured by Lowenstein's method on his medium. Although Abt³³ claims reliability for Lowenstein's method, Cummings³⁴ reports negative blood cultures on both Hohn's and Lowenstein's mediums. Weatherall³⁵ was unable to substantiate Lowenstein's work. Wallgren³⁶ states the necessity for specialized technic if positive blood cultures are to be obtained. Additional study of Lowenstein's medium in the present investigation proved that it supported only scanty growth of tubercle bacilli even when inoculated with large amounts of stock cultures.

For standard work, therefore, these various mediums were rejected in favor of Corper's, Hohn's and Miraglia's mediums. These do not require elaborate preparation and prove to be efficient.

MEDIUMS

Hohn's medium was made according to standard methods.¹⁷

Corper's medium was made according to his standard method.¹⁴

The preparation of Miraglia's medium is described here because this method differs in its extreme simplicity from standard methods described elsewhere.

Miraglia's medium originally consisted of seven egg yolks in 100 c.c. of a 5 per cent glycerol beef broth. More recently, in accordance with the work of Feldman,²³ a 6 per cent glycerol water solution has been substituted for the broth. However, no change in results has been noticed.

The eggs are sterilized by immersing in 60 per cent alcohol for ten minutes. Sterilize the hands, break the eggs quickly, separate the whites from the yolks, and drop the yolks into a large sterile flask with a wide mouth. If the flask is sufficiently large, the egg yolks will break as they hit the bottom and thus eliminate stirring, an obvious element in contamination. Previously sterilized and measured broth is then added, the mixture well shaken, tubed under sterile conditions and coagulated in an Arnold or oven at 90° C. Medium made by this simple method has always been found to be sterile.

PROCEDURE

All specimens except stools, sputums, and tissues were cultured and if sterile were inoculated without further treatment onto tubercle bacillus mediums. Contaminated specimens must be treated with some reagent. The more common ones in use are 5 per cent oxalic acid, 6 per cent sulphuric acid, 15 per cent sulphuric acid, 3 per cent sodium hydroxide, 3 per cent hydrochloric acid, 3 per cent acetic acid, or antiformin. In the present study one-half of the specimens were treated with 6 per cent sulphuric acid and the other half with 5 per cent

oxalic acid. Both reagents appeared to give equally efficient results. Fifteen per cent sulphuric acid was used to kill the contaminating organisms in stools.

Stools, sputums, tissues, and contaminated materials were treated with equal parts of the reagent for one-half hour at 37° C. Solid specimens were ground in a mortar with the reagent. The treated material was then centrifugalized for one-half hour, washed with sterile physiologic saline solution, recentrifugalized and the sediment inoculated onto the mediums with a pipette. Blood specimens were treated according to Lowenstein's method before inoculation. Four or five drops of sediment were smeared over the surface of each tube of medium and at least four tubes of each medium were inoculated for each specimen. The tubes were sealed by pipetting approximately 2 c.c. of melted paraffin on each plug; the tubes were capped with tinfoil. All cultures were incubated in covered tin cans for four months at 37° C. in an incubator before being discarded. Smears were made periodically and again just before the cultures were discarded.

Table III summarizes the results obtained using Corper's, Hohn's, and Miraglia's mediums. Nineteen specimens were received from patients with clinical diagnosis of tuberculosis. Fifteen specimens yielded positive growth on at least one medium. Five were positive on all three mediums; four were negative on all three. Two of these four negative specimens did not produce tuberculosis when injected into the guinea pigs. Two were blood specimens which were not inoculated into guinea pigs. Three specimens were positive on Miraglia's alone, two on Corper's alone, and one on Hohn's alone. One specimen gave a positive growth on both Hohn's and Corper's mediums and three were positive on both Hohn's and Miraglia's. In this series a total of eight specimens gave positive growth on Corper's medium, ten on Hohn's medium, and eleven on Miraglia's medium.

Fifteen specimens from patients with a clinical diagnosis other than tuberculosis gave no growth of tubercle bacilli on the three mediums.

Sixty-seven specimens were received with clinical diagnoses unknown. Of these, 62 were negative. One specimen gave positive results on all three mediums, one each on each of the three mediums, one each on each of the three mediums alone, and one, on Hohn's and Miraglia's only.

These results would lead to the conclusion that Corper's medium is less favorable to the growth of the tubercle bacillus than are the other two mediums. Corper's medium, however, showed contaminations in only 5.2 per cent of tubes inoculated, Hohn's in 13.6 per cent, and Miraglia's in 19.4 per cent.

For further comparison of mediums a second series of 68 specimens were cultivated on Corper's medium and on Miraglia's medium. Table IV summarizes the results obtained in this study.

Five specimens were from tuberculous patients. Tubercle bacilli from one of these grew on both Corper's and Miraglia's mediums. One was positive on Miraglia's alone; 3 were negative on both mediums. Of the total 5, one was positive on Corper's and 2 on Miraglia's medium.

Six specimens tested were obtained from patients with a clinical diagnosis other than tuberculosis. All 6 specimens were negative for tubercle bacilli when cultured on both mediums.

Fifty-seven specimens were received with diagnoses deferred or unknown. Fifty-four were negative when cultivated on both mediums. One was positive on Miraglia's alone, and 2 were positive on both Miraglia's and Corper's

TABLE IV

A COMPARISON OF CORPER'S AND MIRAGLIA'S MEDIUMS FOR THE ISOLATION OF THE TUBERCLE BACILLUS

DIAGNOSIS	MATERIAL	NUMBER OF SPECIMENS	CORPER'S MEDIUM	MIRAGLIA'S MEDIUM

	Urine	1	+	+
	Spinal fluid	1	+	+
	Spinal fluid	1	-	+
	No. Positive		2	3

mediums. A total of 2 were positive on Corper's and 3 on Miraglia's medium. In this series the percentage of contaminated cultures was approximately 5 per cent for Corper's and 10 per cent for Miraglia's medium.

From these results it is apparent that the egg mediums are more sensitive than Corper's medium for the isolation of tubercle bacilli. However, since Corper's medium becomes contaminated much less often than Hohn's or Miraglia's, it should be included as a control medium in routine cultures.

As has been emphasized, the time element is important in the laboratory demonstration of tubercle bacilli. Positive results were obtained by guinea pig injection occasionally in twenty-one days, but the average period was sixty days. Cultures on egg mediums were quite often macroscopically positive in seven days; the average number of days in which positive cultures were ob-

TABLE V

METHOD	MINIMUM NUMBER OF DAYS FOR GROWTH TO APPEAR	AVERAGE NUMBER OF DAYS IN WHICH GROWTH APPEARED
Positive guinea pig inoculations	21	60
Positive cultures on Corper's medium	25	38.5
Positive cultures on Hohn's medium	7	27.7
Positive cultures on Miraglia's medium	7	30.7

tained on Hohn's medium was 27.7 days and on Miraglia's 30.7 days. This substantiates the previous statement that the low percentage of contaminated cultures obtained with Corper's medium is the most important reason for its use in routine work. These statements are summarized in Table V.

SUMMARY AND CONCLUSIONS

A comparison of direct smear, guinea pig inoculation and culture methods for the demonstration of tubercle bacilli in various types of specimens indicated culture methods to give a greater percentage of positive results more quickly than either of the other two methods.

A study of various mediums for the isolation of the tubercle bacillus proved the three simple mediums, Corper's, Hohn's and Miraglia's, to be suitable for routine diagnostic cultures. Hohn's and Miraglia's mediums gave larger numbers of positive results in less time than did Corper's medium. Either of these two mediums may be used with equal efficiency. Corper's medium, however, is sufficiently sensitive and becomes contaminated less often than the egg mediums and, therefore, should be included in routine culture methods.

MODIFIED TECHNIC FOR MAKING WRIGHT'S BLOOD STAIN*

Z. BERCOVITZ, M.D., PH.D., PYENGYANG, CHOSEN (KOREA)

THE object of this note is to suggest a slight modification in the technic for making the usual Wright's stain of a blood film. The apparatus requires two staining jars with covers. The reagents are pure methyl alcohol and Wright's stain† diluted up to 30 per cent with distilled water.

One staining jar is filled with pure methyl alcohol. The second contains the 30 per cent solution of Wright's stain. The blood film is made and dried in the usual manner. It is then immersed in methyl alcohol for at least five minutes. The slide is then placed in the stain for from two or three minutes up, depending upon the intensity of the stain desired. The slide is then washed as usual.

Using this technic there is no precipitation on the slide. It has been found that this method is economical. The stain can be used repeatedly instead of only once as in the usual technic. When the fluid level of the reagents becomes low more is added until there is enough to cover the slide. It is not necessary to discard any of the stain. Even though the solutions are used for several months staining takes place with good results. Even though the slide is in the methyl alcohol for an hour or more, there is no change in the staining properties of the cells.

*From the Pyengyang Union Christian Hospital.

Received for publication, January 11, 1933.

†The Wright's stain used in this study was prepared by dissolving one tabloid (Burr's Welcome Co.) in 10 c.c. pure methyl alcohol.

DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

DIPHTHERIA: A Differential Culture Medium for *B. diphtheriae* and *B. pseudodiphtheriae* (Un Nuovo Metodo Culturale per la Differenzazione Del Bacillo Difterico Dai Bacilli Pseudodifterico), Bruschetti, G. Diagn. E. Techn. di Lab. 4: 212, 1933.

On this medium the diphtheria bacillus, fermenting glucose, produces a greenish color; in the absence of glucose-fermenters the medium shows a yellowish tinge. Because of its lack of specificity, the method is not reliable for direct isolation.

Preparation of Medium.—

1. Immerse a fresh egg in 1:1000 bichloride of mercury solution for 1 hour.
2. Place the egg "in alcohol" (per cent not stated) for 2 hours.
3. Dip one end of the egg in ether which is then burned off in the flame.
4. With a sterile pipette puncture the shell and transfer the contents to a sterile, glass-stoppered bottle (150 c.c.).
5. Add an equal volume of sterile "creamless" (skimmed?) milk and shake vigorously for ten minutes.
6. To 60 c.c. of this mixture add the following with sterile precautions.

Beef serum, sterile	60 c.c.
Glycerin	5 c.c.
2% sterile solution of glucose	5 c.c.
2% sterile solution malachite green	5 c.c.

7. Mix by shaking five minutes, place in sterile tubes, slant, and coagulate in an inspissator.

VACCINES: Comparison of Relative Values of the Intracutaneous Skin Test and of the Pathogen-Selective Culture in Selecting Bacteria for Vaccines From Mixed Cultures, Solis-Cohen, M. Am. J. Clin. Path. 3: 305, 1933.

There is practically no difference between the reactions produced by intracutaneous injections of organisms that are able to grow in the patient's fresh, whole, coagulable blood and the reactions produced by organisms that are killed by his blood.

There seems to be no correspondence between absence of bactericidal power in the blood of the host against a given organism and production in that host of a positive reaction by the intracutaneous injection of such organism.

There probably is no relationship between hypersensitiveness in the host to the exogenous and endogenous toxins of a given organism and the pathogenicity of such organism for that host.

It is questionable whether intracutaneous tests can identify, in a mixed culture, the bacteria that are infecting the patient.

Therefore, intracutaneous skin tests are probably unreliable for selecting bacteria in the preparation of vaccines.

MILK, A Study of the Brom-Thymol-Blue Reaction in Freshly Drawn, Bryan, C. S. Am. J. Pub. Health 23: 721, 1933.

Apparently there are normal physiologic factors that are responsible for a variation in the pH of freshly drawn milk.

The test cannot be used alone to detect cases of mastitis, since positive reactions were obtained in animals that were always free of mastitis. No definite cause is given for these

positive reactions. The work of Hucker, et al., was confirmed, indicating that a negative brom-thymol-blue reaction does not assure freedom from mastitis.

The brom-thymol-blue reaction is of value as an aid in determining the relative disease or freedom from mastitis of a herd. If a large number of positive reactions are obtained it is a good indication that something is wrong in the herd but the individual cases cannot be detected.

PHOTOGRAPHY: The Invisible Photographic Screen, Harding, F. R. J. Biol. Photo. Assn. 1: 203, 1933.

At the Children's Hospital has been developed what might be termed the "invisible screen," because the patient never sees it. It consists of a piece of thin celluloid the same size as the negative that is to be used. This sheet of celluloid is scored with cross-hatched lines one-quarter inch apart. The scoring is done with a scribing tool or the point of a knife. Care must be taken not to cut too deeply or the celluloid will split if it is bent. After the scoring is completed, red or black wax crayon is rubbed into the lines, and the sheet polished with a soft cloth.

To use the screen, lay it on the glass of the printing machine, place the negative on top of it and make the print in the usual manner. The result will be a positive covered with fine white, crossed lines.

As a guide in registering the screen with the negative, a thin, true vertical line is made on the background. This line should show somewhere on the negative. When ready to print, simply register the background line with one of the screen lines.

TUBERCLE BACILLI, Nutrient Quality of Eggs for Growing, Corper, H. J., and Cohn, M. L. Am. J. Hyg. 18: 1, 1933.

Quantitative evaluation of inspissated egg yolk as contrasted with the inspissated white of egg shows the latter to be a poor nutrient for small numbers of tubercle bacilli as compared to the former. The inspissated yolk has also proved slightly superior to the inspissated whole egg.

The addition of broth is not essential to the nutrient qualities of whole egg or egg yolk media. The inspissation of egg or egg yolk media is beneficial to the nutrient qualities and insures sterility as compared to the use of raw unsterilized whole egg or egg yolk.

The addition of a non-nutrient substance such as agar does not introduce any beneficial action upon the nutrient qualities of whole egg or egg yolk media, and if added in too great amount diminishes their nutrient value for small numbers of bacilli.

The addition of water up to 25 per cent to egg yolk before inspissation serves to fulfil the purpose of preventing drying of this medium during the long period of incubation required for the growth of tubercle bacilli.

Mixing of two good nutrients for tubercle bacilli such as egg yolk and potato does not serve to enhance the nutrient qualities of either of these substances but may change the type of colony.

Large plantings of tubercle bacilli grow on a wide range of acidity in good nutrient media such as egg yolk, but a few bacilli require an acidity of narrower range approximating the neutral point.

The value of dyes intimately mixed, with a nutrient such as egg yolk is mainly to assist in the ease of finding early colonies, but they must be used cautiously in a concentration which exerts no tuberculostatic action in graded planting tests. Several pigments and dyes are adapted to this purpose.

SERUM CALCIUM, In Normal Boys, Molitch, M., Weinstein, S., and Cousins, R. F. Am. J. M. Sc. 186: 378, 1933.

The serum calcium findings on 511 normal boys, between the ages of eight and twenty years, range from 7.6 to 12.5 mg. per cent. Of the total number reported, 33 were found

below and 1 above the extreme normal limits of 8.6 and 12 mg. per cent. Disregarding the highest and lowest 5 per cent of distribution, the normal limits are from approximately 8.5 to 10.8 mg. per cent. No progressive decrease was found with age in this group. Nationality and race showed no influence on serum calcium metabolism.

BLOOD CHEMISTRY: Serial N P N Studies and Their Prognostic Significance in Acute Coronary Occlusion, Steinberg, C. L. *Am. J. M. Sc.* 186: 372, 1933.

From a study of 16 cases it is concluded that (a) a rising nonprotein nitrogen or (b) a nonprotein nitrogen that remains elevated in the blood plasma is of ill omen.

More attention should be paid to blood chemistry studies during coronary occlusion as a prognostic aid.

A lowering of the blood pressure and diminution in urine output will not alone explain the rise in nonprotein nitrogen in acute coronary occlusion.

HYPERGLYCEMIA, Hypertension, Obesity and, Musser, J. H., and Wright, D. O. *J. A. M. A.* 101: 420, 1933.

A group of thirty obese hypertensive women exhibited a marked lowering of sugar tolerance. A second group of fat individuals without hypertension are shown not to have a hyperglycemia. It seems reasonable to assume that there is no one factor definitely responsible for the combination of obesity, hypertension and hyperglycemia unless it is obesity. The reduction in weight is often associated with a lowering of the blood pressure and a return of a sugar tolerance curve to normal.

PNEUMONIA, Value of Skin Test With Type-Specific Capsular Polysaccharide in the Serum Treatment of Type I Pneumococcus Pneumonia, Francis, T., Jr. *J. Exper. Med.* 57: 4, 617.

Skin tests were made with Type I S.S.S. in 53 cases of Type I pneumococcus lobar pneumonia, 48 of which were treated with antipneumococcus Type I serum. In all but 1 of the 46 recovered cases a positive, immediate skin reaction was obtained at about the time of recovery. In 7 fatal cases reactions were consistently negative, even in the presence of circulating type-specific antibodies.

The skin test has proved to be an extremely valuable guide to serum therapy, and a definite prognostic aid. The test has distinct advantages over the agglutination reaction in that it is not merely an index of circulating antibodies. When positive, it invariably denotes that recovery has begun; when negative, it indicates further serum therapy. The mechanism of the positive skin test is closely related to that operative in recovery from pneumonia, and is apparently the resultant of antibody and tissue activity.

TUBERCULOSIS, Gastric Examination in Pulmonary Tuberculosis With Negative Sputum Examination, Ulmar, D., and Ornstein, G. G. *J. A. M. A.* 101: 835, 1933.

A search was made of the gastric contents for tubercle bacilli in pulmonary tuberculosis. The mechanism of bronchial peristalsis is demonstrated whereby bronchial contents are raised to the level of the larynx without the mechanism of cough. The importance of this mechanism in raising sputum from the lungs is amply shown by the fact that, in a series of 287 cases in which there were repeated negative sputum examinations, approximately 20 per cent yielded tubercle bacilli on examination of the gastric contents. In some of those positive cases there was no previous coughing and expectoration. The importance of this method of investigation becomes increasingly significant when the normal cough mechanism has been interfered with as, for example, in pneumothorax or thoracoplasty cases. The simplicity of the examination, which consists merely in the usual concentration technic on the aspirated gastric contents, makes the examination so easy as to warrant its routine use in all suspected sputum negative cases.

HEPATIC FUNCTION: Clinical Values of Levulose and Galactose Tolerance Tests for, Radhakrishna, M. V. Ind. J. M. Res. 21: 141, 1933.

From this study it is concluded that the levulose tolerance test gave positive results in a greater number of cases with liver disease than in those without evidence of hepatic disorder. In some cases with definite evidence of liver disease the test gave negative results, and hence it is concluded that the test cannot be considered to be of diagnostic importance in any individual case.

The variable results obtained by the levulose tolerance test in cases of cirrhosis of the liver are considered to be due to the regeneration of the hepatic tissue. It is pointed out that a negative test in these cases cannot exclude liver disease, as it only indicates that a sufficient amount of actively functioning liver tissue is still left to maintain the carbohydrate metabolism. The test becomes positive only when there is diffuse destruction of the hepatic parenchyma together with failure of regeneration.

Though the galactose tolerance test of Bauer has its own advantages, it is misleading to depend on the urinary findings alone and the total amount of galactose excreted in the urine is too variable to consider it as a guide to hepatic efficiency.

ENDO MEDIUM, Nature of Reaction of Colon Organism on, Margolena, L. A., and Hansen, P. A. Stain Techn. 8: 131, 1933.

Considerable confusion in the understanding of Endo's reaction is caused by the fact that a faint coloration may be produced by weak acids and by oxidations, both causing a restoration of the fuchsin color.

The viewpoint of Neuberg and Nord that the cultivation on the Endo medium is a trapping procedure (Abfangverfahren) for acetaldehyde is confirmed.

The typical reaction of *Bacterium coli* is caused not by lactic acid, but by the intermediate product acetaldehyde which is fixed by sodium sulphite.

The color produced in the reaction is not restored fuchsin, which is shown by the fact that it cannot be shaken out with ether when picric acid has been added beforehand.

TYPHOID CARRIERS, Serological Diagnosis of, Wyllie, J. Am. J. Hyg. 78: 393, 1933.

In any agglutination method using living bacterial suspensions the pitfalls are due to the S R variation and to the H O variation. The former variation is easily detected by the appearance of spontaneous agglutination (granular in type) in increasing strengths of saline controls. A slight granularity in 0.85 per cent saline is more marked in 1.7 per cent and more so in 3.4 per cent and 6.8 per cent saline. When this occurs the stock culture is replated on agar and a smooth colony picked off. In this way the colony form is taken as an indication of smoothness or roughness and this is afterward examined for physiologic smoothness or roughness.

The latter variation (i.e., H O) is guarded against by subculturing the "H" variants on agar slants containing some water of condensation. O variants may be subcultured on dry agar slopes. The agar medium must be carefully prepared as outlined on pages 395 and 396 and the use of motility tubes containing semisolid agar ensures maximum development of the H-receptors. Felix (1931) recommends however that agar stabs for maintaining stock cultures over long periods should not contain muscle sugar, hence this agar should be prepared from meat extracts instead of fresh meat.

In this study of the serologic reactions of typhoid carriers by Felix' method, the sera were examined qualitatively with living bacillary suspensions of "H" and "O" strains of *B. typhosus* and *B. para-typhosus* A and B. In the large majority of these sera "O" agglutinins were found exclusively. The typhoid H suspension of the Oxford Standards Laboratory, however, revealed the presence of "H" agglutinins in nearly all of these sera.

The use of living typhoid and paratyphoid strains necessitated particular care to maintain the cultures in the optimum phase. The results show that sufficient differences in the type and degree of agglutination in the three classes of sera studied—from typhoid

carriers, from typhoid fever cases and from individuals receiving prophylactic inoculation—justify the opinion that an additional serological procedure is available to assist in distinguishing carriers from normal and from inoculated individuals.

TUBERCULOSIS, Effect of Exercise on the Leukocyte Count in Pulmonary, Kaminsky, J.
Am. J. M. Sc. 186: 484, 1933.

In 50 tuberculous patients leucocyte counts were made after one hour's rest in bed and the results compared with those of blood counts taken after some exercise.

Thirty-eight cases showed an increase in their total counts following exercise (increases of more than 2,000 cells were obtained in 19 cases); 12 cases showed a decrease in their total counts taken after exercise.

Striking variations were noted in some of the differential counts taken after exercise; increases in the cells of some types exceeding 100 per cent were encountered.

The value of performing leucocyte counts under basal conditions in the study of cases with pulmonary tuberculosis is emphasized.

RETICULOCTES: A New Method of Enumeration, Schleicher, E. M. Am. J. Clin. Path. 3: 395, 1933.

Solution A

Neutral potassium oxalate	1.0 gram
Sodium chloride c. p.	0.85 gram
Distilled water	100 c.c.

Solution B

Brilliant cresyl blue	1.0 gram
Sodium chloride c. p.	0.85 gram
Distilled water	100 c.c.
Chloretone (as a preservative)	1.0 gram

In a conical tipped centrifuge tube place 25 parts of Solution A and 5 parts of Solution B, mix (since a precipitate forms when the solutions are mixed, it is better to make up a larger volume, filter and place the proper amount of the mixed solution in the tube and proceed), and add several drops of blood. After thoroughly mixing, permit to stand ten to twenty minutes, then centrifugalize for twenty to thirty seconds at a moderate speed. The supernatant fluid is pipetted off until a layer of fluid approximately equal to the depth of the sediment remains. Mix the sediment well with the supernatant liquid, draw up in the pipette and discharge one drop near the end of a perfectly clean glass slide.

Spread the stained drop with the edge of a coverslip square 18 mm. and draw the film to about 6 cm. from the starting point.

The underlying principle of the method involves the Relative Reticulocyte Distribution (R.R.D.) throughout the smear. To know the relative distribution of reticulocytes is important, since it is technically not possible to make a blood film manually so that the distribution of erythrocytes and reticulocytes is equal throughout the preparation. It has been determined, however, that the distribution varies in a definite way when the above technic of preparing smears is followed each time.

The R. R. D. is found as follows: Divide a piece of paper into 10 columns and mark them 1 to 10. Adjust a 4x eyepiece to a tube-length of 190 mm., using an oil immersion objective 1.8 mm. x 95 N.A. 1.30 in order to obtain the specific microscopic working field. Any other combination giving the same field may be used.

The R. R. D. in the film will usually be found to show about four variations in concentrations as follows: (1) extremely high, (2) high, (3) low, (4) extremely low or absent.

Place the objective on the upper edge of the film near the starting point, that is, the extreme left border of the film. Moving the slide upward in a vertical line, count several

RETICULOCYTES: A New Method of Enumeration, Schleicher, E. M. Am. J. Clin. Path. 3: 395, 1933.

Solution A

Neutral potassium oxalate	1.0 gram
Sodium chloride c. p.	0.85 gram
Distilled water	100 c.c.

Solution B

Brilliant cresyl blue	1.0 gram
Sodium chloride c. p.	0.85 gram
Distilled water	100 c.c.
Chloretone (as a preservative)	1.0 gram

In a conical tipped centrifuge tube place 25 parts of Solution A and 5 parts of Solution B, mix (since a precipitate forms when the solutions are mixed, it is better to make up a larger volume, filter and place the proper amount of the mixed solution in the tube and proceed), and add several drops of blood. After thoroughly mixing, permit to stand ten to twenty minutes, then centrifugalize for twenty to thirty seconds at a moderate speed. The supernatant fluid is pipetted off until a layer of fluid approximately equal to the depth of the sediment remains. Mix the sediment well with the supernatant liquid, draw up in the pipette and discharge one drop near the end of a perfectly clean glass slide.

Spread the stained drop with the edge of a coverslip square 18 mm. and draw the film to about 6 cm. from the starting point.

The underlying principle of the method involves the Relative Reticulocyte Distribution (R. R. D.) throughout the smear. To know the relative distribution of reticulocytes is important, since it is technically not possible to make a blood film manually so that the distribution of erythrocytes and reticulocytes is equal throughout the preparation. It has been determined, however, that the distribution varies in a definite way when the above technic of preparing smears is followed each time.

The R. R. D. is found as follows: Divide a piece of paper into 10 columns and mark them 1 to 10. Adjust a 4x eyepiece to a tube-length of 190 mm., using an oil immersion objective 1.8 mm. \times 95 N.A. 1.30 in order to obtain the specific microscopic working field. Any other combination giving the same field may be used.

The R. R. D. in the film will usually be found to show about four variations in concentrations as follows: (1) extremely high, (2) high, (3) low, (4) extremely low or absent.

Place the objective on the upper edge of the film near the starting point, that is, the extreme left border of the film. Moving the slide upward in a vertical line, count several

fields that show the highest as well as the moderately high, moderately low and low reticulocyte concentrations. Record the counts of each classification in column 1. When the lower edge of the film is reached, move the slide to the left horizontally 0.5 cm. (measured by the mechanical stage), from this point move the slide downward, count the reticulocyte concentrations as before and record them in column 2. Count ten vertical zones in this manner. If a vertical zone does not show any reticulocyte, mark in the corresponding column a zero.

In a vertical zone 18 mm. in length there will be found approximately 150 microscopic fields, the average field showing about forty erythrocytes. There should be counted and recorded in each column the number of reticulocyte concentrations found in at least eight to ten fields in each vertical 18 mm. zone. Select from the 80 to 100 individual enumerations recorded in the ten columns ten reticulocyte counts distributed as follows:

(a) Two fields showing extremely high concentrations.

(b) Three fields showing high concentrations.

(c) Two fields showing low concentrations.

(d) Three fields showing extremely low to absent concentrations (when selecting the individual reticulocyte counts use as many zeros as there have been zero columns).

Having added the ten reticulocyte counts the total number is referred to as the sum of reticulocytes (S_R). In the same ten fields there are 400 erythrocytes. The ratio of reticulocytes to erythrocytes is therefore S_R

The percentage of reticulocytes is $\frac{S_R}{400}$

$\frac{400}{400} \times 100$

or per cent = $S_R \times .25$

TUBERCULOSIS, Sanocrysin Treatment, Henrichsen, K. J., Sweany, H. C., and Hruby, A. J. Am. Rev. Tuberc. (Suppl.) 28: 1, 1933.

About 50 per cent of tuberculous patients having a stationary or downward progressive advanced tuberculosis of the "B" or "C" types, when given Sanocrysin in well-regulated doses, will show (1) a rather prompt cessation of symptoms (drop of temperature and pulse, increase of weight, and improvement of general condition), which changes tend to be permanent if the patient observes the usual measures of hygiene; (2) a clearing of tuberculous infiltration, with marked fibrosis and contraction of cavities, as shown by roentgenograms; and (3) changes from unfavorable to favorable laboratory findings.

The remainder of the treated patients may be divided about equally into three classes: those who show a temporary improvement for a few weeks to a few months; those who show no favorable change; and those who will not tolerate the drug at all.

By all the methods of control available and carefully analyzed figures, we can conclude that there is a shortening of the convalescent period or prolongation of life or both in the treated patients of Group 1.

There seems to be a real indication for the drug's use as a supportive treatment in collapse therapy when patients are not doing well, and when there is a beginning spread to the other side, or when there is need to clear up a slight involvement of one side in preparation for collapse therapy on the other.

Sanocrysin may be used to speed the convalescence of patients with favorable prognosis, but this is usually unnecessary.

The drug may be added to the armamentarium of the tuberculosis specialist for use when other measures are unavailable, as well as for other "reacting" types when the skill of the physician is able to direct a successful course.

More experiment is warranted, so that indications, or contraindications, and more favorable types may be better established, in all ages, stages, complications, types of the disease, and in both sexes.

AGGLUTININS: The Agglutinin Content of the Blood Following Typhoid and Paratyphoid Immunization. Foord, A. G., and Forsyth, A. *Am. J. Clin. Path.* 3: 333, 1933.

Agglutination tests conducted simultaneously with the same flask of antigen on serums of 120 nurses and internes immunized by three weekly subcutaneous injections of triple typhoid paratyphoid A and B vaccine furnished by the New York State Department of Health revealed the presence of typhoid agglutinins in a dilution averaging 1:320 to 1:640 at the end of twenty-three days following the last injection.

Tests at longer intervals of several months and to from five to nine years demonstrated persistence of agglutinins in all the serums studied in lower, but clinically significant amount; for example, 1:160 after six and nine years, respectively.

Agglutinins against paratyphoid bacilli were demonstrated at titers averaging somewhat lower than the corresponding titer against the typhoid bacillus.

In evaluating a positive agglutination test against typhoid or paratyphoid organisms, the history of prophylactic immunization must be considered, even though many years have elapsed since the inoculations.

PREGNANCY: The Rabbit Ovulation Test, Anklesaria, S. B. *J. Univ. of Bombay* 1: 108. 1933.

All the biologic tests of pregnancy depend on the presence, in the body, of living chorionic tissue in biologic contact with the blood stream.

Pregnancy is a physiologic condition in which chorionic tissue is present and is in contact with the blood stream; but should a man or woman be the unfortunate possessor of a tumor containing chorionic tissue, i.e., a chorioneplithelioma, he or she should give a positive biological test. Thus its use in the diagnosis of these tumors both in the female and in the male in the testis for example, is quite apparent.

In normal pregnancy the test is positive as early as three weeks after conception. It becomes negative in two to seven days after puerperium, the rabbit ovulation test becoming negative earlier (forty-eight hours).

In abnormal pregnancy the tests are useful in the diagnosis of ectopic gestation, abortions in various phases, and hydatidiform mole.

In ectopic gestation the test remains positive so long as there is a certain amount of living chorionic tissue in biologic contact with the maternal tissues. The author found it repeatedly useful and in only one case out of seven was it negative; this case being of long standing with no living chorionic tissue. In such cases, however, the danger of ectopic gestation is much less. The author shall, however, emphasize the fact that a full dose of 24 c.c. of urine and a forty-eight-hour interval between the first injection and the laparotomy will go a great way in diminishing the number of negative results.

In cases of death of the ovum in uterine pregnancy, the reaction takes some time to become negative, the time being greater in advanced gestation; it may take as long as a month or more. The significance of a positive reaction becoming negative is great in diagnosing death of the ovum.

Though the reaction disappears within forty-eight hours or a little more in the normal puerperium, it takes two months or a little more to disappear after the passage of a hydatid mole, though the mole may not be malignant.

In cases of hydatid mole and chorioneplithelioma, the author has found the test positive with very small amounts. He is determining at present the smallest quantity of urine that would give a positive reaction in normal pregnancy, which work will be published in a future paper.

TUBERCLE BACILLI, Heavy Drop Method for Demonstration of, in Sputum, Kornetov, I. *Klin. Med. Moscow* 11: 109, 1933.

A particle of the suspected sputum is placed in the center of the glass slide. The amount is determined by its consistency. If the sputum is fluid, a particle about 10 mm. in diameter may be used; if it is thick, a particle of a diameter not exceeding 5 mm. is

used. Five drops of a mixture of 20 c.c. of 10 per cent ammonium hydroxide solution and 30 c.c. of 96 per cent alcohol are added. By means of a thin glass rod the sputum and solutions are mixed. In a few minutes five more drops of the mixture are added as before. If a homogeneous mass has not been obtained, five more drops are added. After five minutes the mass is usually homogeneous. The mixture is then dried in an autoclave or an incubator. The preparation dries in the air in two to three hours, under proper temperature in about twenty minutes. Excessive heating should be avoided. The dried mass is stained without fixation. Sufficient carbolfuchsin to cover the mass is added. The slide is heated until it steams; this procedure is repeated twice and the carbolfuchsin is decanted. The preparation is treated repeatedly with 5 per cent nitric or sulphuric acid, the acid being washed off each time, so that finally the preparation assumes a slight rosy color. The preparation is then treated with a few drops of a 1 to 500 solution of methylene blue or a few drops of a 1 to 500 solution of chrysoidin. The slide is washed and dried.

By this method each field contains from 6 to 20 times more tubercle bacilli, if such are present, than the usual smear.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor, Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

The History and Epidemiology of Syphilis*

THIS book is a series of three lectures delivered under the Adolph Gehrman endowment at the University of Illinois College of Medicine in March, 1933. The first lecture discusses the origin of the disease, presenting the evidence for and against its importation into Europe by the sailors of Columbus. The second lecture summarizes the historical development of our understanding of the nature of the disease and its treatment. The third discusses present epidemiologic problems and outlines preventive possibilities. For further discussion see editorial in this number.

The History of Dermatology†

IT IS only within the last hundred years that dermatology has become a specialty. As the author remarks, the history of dermatology, especially prior to 1800, is the history of medicine in general. He has, however, abstracted from the history of medicine the points that are of particular interest in connection with dermatology and the first sixty odd pages are devoted to the facts of dermatology as they have been developed in the history of medicine up to the beginning of the nineteenth century. The second two-thirds of the book deals with the historical development of dermatology as a specialty. This has been done in a very readable and informative way. Sometimes the reader wishes the author had more space to devote to the development of the personalities of the men who contributed so much to the specialty.

A distinct innovation, as an appendix, is the author's historical index on dermatology. In it he lists the various dermatologic diagnoses alphabetically, with brief summaries describing when such diseases were first mentioned in history, with other outstanding historical points about them.

The Origin of Syphilis

TWENTY years ago it was generally understood that, as far as the civilized world is concerned, syphilis is one of the few new diseases that have been introduced since ancient times. It was understood that the disease was contracted by the sailors of Columbus from the Indians of the New World, carried back into Spain and Portugal from where it rapidly spread to the Spanish soldiers who, as mercenaries, introduced it into the armies of Charles VIII of France and by which it was carried into Italy as far as Naples. The army, victorious against the Neapolitans and others in their pathway succumbed to the disease, retreated into France and there was disbanded, to send syphilis home to all of the countries of Europe which had contributed to the mighty army of Charles. The Italians called it the Spanish disease, the French called it the Italian disease, the English, Germans and Turks called it the French disease and the Russians called it the Polish disease. The Spanish, alone, called it the disease of Haiti.

Aside from the time relationship, epidemiologic considerations pointed to an infection of a previously uninvaded multitude of hosts whose lack of acquired immunity was chiefly responsible for the extreme virulence of the epidemic.

But in 1913 Karl Sudhoff presented his evidence that syphilis had existed in Europe prior to Columbus' discovery of America. This opened the question anew with the result that some evidence was collected through several years purporting to show that syphilis was an ancient disease in Europe, even that the ancient Egyptians had suffered from syphilitic osteitis, as evidenced by lesions found in mummies. Probably it is well that the question was raised by an authority such as Sudhoff, since this necessitated a reexamination of the records and has resulted in the discovery of additional facts far more convincing than those previously available. The evidence for and against importation from the New World has been collected and presented by Pusey in a most interesting manner in his Gehrman Lectures before the University of Illinois.¹

In Germany in 1495 syphilis was often mentioned as the "never-before-seen-and-heard-of-disease." The earliest known German state document on syphilis was published in 1495, well after the time of Columbus' return and the introduction of syphilis into Germany.

Oviedo, who was in Barcelona at the time of Columbus' return and knew him and members of his crew, described how the disease was contracted from Indian women by Spaniards with Columbus and how it was brought by them to Spain. Las Casas, whose father accompanied Columbus on his second voyage, and who, himself, lived in Haiti for many years remarked "there were and still are two things which at the beginning were very dangerous to the Spaniards. One was the disease syphilis, which in Italy is known as the French malady." He, himself, describes seeing the first cases in Seville among Columbus' sailors. "It is a thing well verified that all the incontinent Spaniards that did not have the virtue of chastity on this island were contaminated."

Dias de Isla, who was a physician at Lisbon at the time of Columbus' return, described the new disease as it occurred among Columbus' sailors and later in the general population. The first and second editions of his work have been discovered and what is more interesting, the original manuscript. The original manuscript contains certain paragraphs on syphilis which were omitted from the printed work. This may have been for patriotic reasons. Dias de Isla, practicing in Barcelona in 1493, saw the very entrance of syphilis into the Old World. He states definitely that the disease was unknown before the year 1493, that it was brought by the crew of Columbus on their return from their first voyage, that a majority of the crew were infected, and that he himself treated a number of the sailors. "At the time that Admiral don Xristoual Colon arrived in Spain the Catholic Sovereigns were in the city of Barcelona. And when they went to give an account of their voyage and of what they had discovered, immediately the city began to be infected and the aforesaid disease spread."

It has been claimed that bone lesions have been found indicative of syphilis in human beings who died in the Old World long before the discovery of

America. Among others, Williams of Buffalo has made extensive investigations into this. The only incontrovertibly characteristic bone lesion is in the flat bones of the skull. Lesions of long bones might be due to other diseases. No incontrovertible evidence of syphilis of the bone has ever been presented in any skull prior to the time of Columbus except in the New World, where such evidence is relatively abundant. The search therefor has not been haphazard, as is indicated by the report of Elliot Smith based upon the examination of the mummies of 30,000 Egyptians and Nubians.

There is no definite evidence, either from morphologic studies, from historical documents, from medical treatises, or from legal enactments, of the presence of syphilis in Europe prior to the discovery of America. And, as Pusey pointedly remarks, there is no evidence in the prurient literature of the ancients. What fun Boccaccio or the authors of the Arabian Nights would have had in describing the wages of sin did they know of the ravages of syphilis!

But, after the return of Columbus it required but a short time for the disease to spread throughout the known world. The Portuguese explorers lost no time. In India the disease was recognized in 1498, after the arrival of Vasco de Gama who had left Portugal one year earlier. It appeared in Canton, China, in 1505. In Japan it was first described in 1569 when it was imported either by Chinese or Portuguese sailors.

The discovery of a New World gave birth to many new and perplexing problems, not the least among which was that of syphilis.

CORRESPONDENCE

Remarks supplementary to editorial on "Bilirubinemia and Pneumonia" by R. A. K. in
Journal of Laboratory and Clinical Medicine 18: 1197, 1933

To the Editor:

In order to establish a clear understanding of the significance of the jaundice of lobar pneumonia as it may be seen in its present stage of analysis, the following summary is submitted. This summary represents but a single phase of a concept-totality with a number of ramifications involving jaundice as a whole and its mechanism in any other clinical entity with which it may be associated. Here, however, we are concerned specifically only with the events occurring when jaundice is associated with a disease caused by a bile-soluble organism, the pneumococcus.

1. Icterus, manifest in one or all of three tests performed daily during the acute course of lobar pneumonia, has been found to be practically always present. These tests consist of the icterus index, the aqueous (direct) van den Bergh reaction, and the quantitative serum bilirubin determination, based on van den Bergh's application of Ehrlich's diazo reaction as recommended by Pröscher.

2. The visibility of icterus in the skin or sclerae is of no significance other than that visible icterus is quite characteristic of lobar pneumonia, its detection being largely a question of the visual acuity of the observer. The fundamental data must be obtained from studies on the blood serum. Numerous observations have demonstrated that no threshold for the visibility of icterus can be postulated, since visibility is dependent on qualitative as well as quantitative factors in jaundice.

3. If, regardless of other methods for characterizing the course of lobar pneumonia, cases are classified on the basis of the presence or absence of pleural fluid (not fibrin alone), demonstrable by x-ray, daily physical examination, or, preferably, chest tap, then the following conclusions are admissible:

a. Approximately 70 per cent of hospitalized patients with lobar pneumonia in this series developed pleural fluid, and in this group the mortality was approximately 15 per cent.

b. In the remaining 30 per cent of these patients fluid was not demonstrable in any way ("dry chest" type), and in this group the mortality lay between 75 per cent and 80 per cent.

A figure for the incidence of pleural fluid in pneumonia, closely approximating this finding, is reported by G. Andral, *Clinique médicale, Paris, Gabon et Cie., 1824, 2, 242*, and by R. T. H. Laennec, *Traité de l'auscultation, Paris, G. S. Chaudé, ed. 2, 1826*. It is on the basis of the presence or absence of this fluid that the interpretation of the changes in the jaundice of lobar pneumonia is made, so far as they are related to the outcome.

4. In the white race, in the absence of pleural fluid, the mortality has thus far been 100 per cent unless the icterus index exceeded 16.6. Most white patients whose icterus index curves exceeded 16.6 exhibited the downward turn in the zone 18.7 to 30, and thus far none have died whose maximum index lay in this zone whether fluid was present or absent. When, as occasionally happened, the icterus index of a white patient exceeded 30, recovery then took place only if the icterus index 100 was attained. In the negro, on the other hand, in the absence of fluid, the mortality was 100 per cent unless the icterus index exceeded 100. This is why apparently white patients are said to show negroid reactions if their icterus index curves exceed 30. True crisis is regarded as the favorable termination of the disease when fluid is absent. It is rare.

5. Upon the development of pleural fluid the rising icterus index curve is broken, and the curve tends to fall back to normal. Frequently a patient is seen for the first time after this has already occurred, and the icterus index is found to be normal. Jaundice is then

demonstrable only by the van den Bergh reaction, or in an elevation of the quantitative serum bilirubin. These patients die with direct positive van den Bergh reactions, and resolution is not assured until the van den Bergh reaction (by the ring test) becomes negative. In all cases in which data were available to show that, in the presence of fluid, the icterus index curve turned in the zone 11 to 15, thus far there have been no fatal terminations in the white race.

6. The icterus index 16.6 warrants recognition as the "Death Index" in the white race in the absence of fluid, for it must be passed if recovery is to be expected. It may be regarded as a biologic constant in the white race, and of no significance in the negro. The data suggest further that the icterus index 10, apparently of significance in the white race in conjunction with the formation of pleural fluid, is worthy of careful consideration as another possible constant.

In this entire study of icterus, as it occurs in pneumonia and other conditions, it has become apparent that many commonly accepted theories on which classifications of jaundice are based are not acceptable as working hypotheses, hence it is advisable not to attempt to classify the icterus of lobar pneumonia at the present time.

The study of the pneumonic icterus, as well as all icterus, is extraordinarily fascinating, but like all research, requires that the tests be performed by the research worker himself rather than being entrusted to a technician, unless the technician has time and interest to devote to the work specifically. It is further advisable that a single individual conduct the tests, so that the factor of error will be a constant.

In pneumonia, induced by a specific organism, it does not follow that only pneumococcus pneumonias exhibit icterus. It does follow, however, that in pneumonias caused by Friedländer's bacillus, staphylococci, and the hemolytic streptococcus, the interpretation of the movements of the icterus is wholly invalidated, for such organisms are not bile soluble. Blood cultures, x-ray examinations of the chest, sputum cultures, chest and lung punctures and cultures, and autopsies have on several occasions disproved apparent exceptions to the findings described above, especially when erroneous clinical diagnoses were made, or when the invading organism was other than the pneumococcus.

Pleural fluid is generally most conspicuous in patients approaching a fatal outcome in its presence, frequently being very transient in those that recover uneventfully, but is readily demonstrable by timely chest-tap. It may be differentiated from true empyema in that, although it is a cellular fluid, the supernatant is bright yellow as contrasted with the more or less colorless supernatants of empyema, and its cells, as exhibited by supravital staining technic, comprise a relatively high percentage of living macrophages, in contrast with the dead polymorphonuclears of empyema.

CLINICAL AND EXPERIMENTAL

THE MACROPOLYCYTE*

W. E. COOKE, M.D., WIGAN, ENGLAND

THE statement that megakaryocytes are occasionally found in the peripheral blood has been repeated in textbooks and monographs during the past thirty years, but I have never seen in blood films a cell which faithfully resembled the multinucleated giant cell of the marrow; nor have I seen photographs or drawings of the cells so described that are at all convincing.

There is every probability that these so-called megakaryocytes belong to one or other class of macropolycytes.

DEFINITION

The normal neutrophile polymorphonuclear leucocyte, for brevity called the "polymorph," measures, in fixed and stained films 10 to 12 and occasionally up to 14 micra in diameter. In certain conditions giant polymorphs measuring 16 to 20 or more micra in diameter are found, to which the descriptive title "Macropolycyte" is given (1927).

Morphologically there are three types of macropolycytes. The first or Type 1 resembles the other polymorphs in the blood film in that its nuclear structure and fine oxyphil cytoplasmic granules are indistinguishable from those in the polymorph. The only differences from that cell are the large size and frequent hypersegmentation of the nucleus.

The Type I macropolycyte is found: (1) in health; (2) in infections and intoxications where there is bonemarrow reaction, e.g., the acute pyrogenic

*From the Pathological Department, Wigan Infirmary.
Received for publication, December 6, 1932.

infections, tuberculosis, malaria, the exanthemas, carcinoma, myeloid leucemia, and in rabbits with experimental anemia due to ricin or repeated hemorrhages; (3) pernicious anemia.

The Type I macropolyocyte is illustrated in Plate II, Figs. 2 to 7, and in Plate III, Figs. 9, 10, 11, 12, 13, and 14.

The Type II macropolyocyte resembles the megakaryocyte of the marrow in that its nucleus is gnarled and somewhat condensed and may be of the simple horseshoe type, or may have as many as 14 segments. The cytoplasmic granules are coarse and are not all oxyphil as in the polymorph, but azurophil granules are present in varying numbers.

The cell is found in pernicious anemia and is illustrated in Plate III, Figs. 15 to 25.

The third type of macropolyocyte has features of both the preceding types. It resembles the Type I cell in having fine oxyphil granules in the cytoplasm, while the general nuclear conformation is that of Type II. It differs from both in nuclear structure. As the figures on Plate IV show, the nuclear structure is a very open meshwork suggesting a deficiency in basichromatin, and the bulk of the nucleus appears to be large in comparison to the cytoplasm. The nucleus is often rolled and folded on itself, but hypersegmentation is not frequently seen. This type like Type II occurs in pernicious anemia.

THE POLYMORPH IN HEALTH AND IN INFECTIONS

For the better appreciation of the macropolyocyte a few remarks on the polymorph are necessary. The polymorph enters the blood stream from the marrow with a single-lobed nucleus, and as its life in the circulation continues, the nucleus becomes more lobulated until toward the end of its existence it has four or five segments united by fine strands of chromatin (Plate I). In the blood stream, therefore, there are, normally, cells representing the various periods from youth to senility, and it was found by Arneth (1904) that the numbers of polymorphs with one, two, three, four, or five nuclear segments were remarkably constant in health and could be classified on those lines. Our average normal count, that is the percentage of cells in the various classes corresponding to nuclear segments, is:

Class	I	II	III	IV	V
	10	25	47	16	2

This was the average of the counts of 90 normal persons of both sexes between the ages of twelve and fifty-five years. The greatest possible care was taken to exclude infection at the time the blood was taken, and for two months previously. The teeth, throat, nose, ears, chest, abdomen, and urine were examined, and in many cases radiograms were taken of the chest and teeth.

The length of life of the polymorph in the blood stream has been estimated on experimental and clinical grounds (Ponder, 1926) (Cooke and Ponder, 1927) to be approximately three weeks. The figures given above represent a polymorph population comparable to infants, children, men, old men, and senile men, in which the deaths in the older groups are exactly compensated for by the births from the marrow. The figures of the polynuclear count tell us

whenever this normal state becomes altered, whether by the addition of an unusually large number of young cells, by the removal of an unusually large number of old cells, by both these conditions combined, or by some interference with the normal development.

It will be noted that no class is provided for cells with more than five nuclear segments. Such polymorphs are rare in normal blood and when they do occur they are placed in Class V.

In infective conditions the percentage of cells of Classes I and II is increased, and the older cells of Classes IV and V rapidly disappear from the circulation. The count has, therefore, a left-handed drift, as in the following examples:

	I	II	III	IV	V
Normal	10	25	47	16	2
Typhoid fever	54	31	15	—	—
Scarlet fever	44	43	13	—	—
Measles	45	39	16	—	—
Erysipelas	45	40	14	1	1
Diphtheria	41	39	17	3	—
Rubella	30	35	32	3	—
Varicella	33	35	28	4	—
Pertussis	34	39	27	—	—
Puerperal sepsis	42	37	21	—	—
	I	II	III	IV	V
Cerebrospinal fever	40	45	14	1	—
Lobar pneumonia	57	26	15	2	—

These facts make the appearance of the macropolyocyte the more remarkable, because, although a fairly rare cell, it is found in infections frequently associated with a polymorphic leucocytosis and always with a left-handed polynuclear count.

Before proceeding to further discussion, the moment is opportune to suggest that, although the Type I macropolyocyte found in pernicious anemia may be morphologically identical with its prototype found in health and in intoxications, the cause of its appearance is probably very different. For this reason the Type I macropolyocytes of health and of intoxications would be better considered together, and the types found in pernicious anemia classed under the heading "the macropolyocytes of pernicious anemia."

THE TYPE I MACROPOLYCYTE IN HEALTH AND IN CONDITIONS OF ABNORMAL MARROW ACTIVITY

1. *In Health*.—Macropolyocytes are extremely rare in health, no example being seen in the blood films of the 90 investigated normal persons that formed the basis of our average normal count. Recently, however, I observed a macropolyocyte in a man, aged thirty-four years, whose polynuclear count had previously been included in the original 90. He was reinvestigated, but no focus of infection could be found. The counts of the two occasions were almost identical:

I	II	III	IV	V
11	31	42	14	2

The count has a weighted mean of 2.65, which falls close to the average mean of 2.74, and within the limits of normality. I think we must accept the fact that macropolycytes do very occasionally appear in normal blood films.

2. *In Conditions of Abnormal Marrow Activity.*—This type is illustrated by the Figs. 2 to 7 in Plate II.

PLATE I.

The five classes of the polynuclear count. If there is any band of nuclear tissue except a chromatin filament, uniting the nuclear masses, those parts must not be considered as separate segments. Class I, No. 2, Class II, Nos. 3 and 4, Class III, No. 4, Class IV, No. 5, illustrate this point. In Class V, No. 4, the upper segment of the nucleus overlies the segment below it, but the thin chromatin filament uniting them can be seen on the left.

Plate II. Fig. 2 is a macropolycyte found in a case of staphylococcal osteomyelitis, which had the following blood count:

Total leucocytes	18,000 per c.mm.
Polymorphs	87 per cent.
Polynuclear count	41, 43, 15, 1, 0.

Plate II. Fig. 3 is a macropolycyte from a case of streptococcal septicemia.

Total leucocytes	26,000 per c.mm.
Polymorphs	79 per cent.
Polynuclear count	34, 43, 21, 2, 0.

Plate II. Figs. 4 and 5 are macropolycytes from a case of mixed infection by *Staphylococcus aureus* and *Bacillus coli*.

Total leucocytes	23,700 per c.mm.
Polymorphs	88 per cent.
Polynuclear count	45, 39, 15, 1, 0.

Plate II. Fig. 6 shows a macropolycyte from a case of streptococcal endocarditis.

Total leucocytes	16,000 per c.mm.
Polymorphs	76 per cent.
Polynuclear count	39, 34, 27, 0, 0.

PLATE II.

Fig. 1.—A normal polymorph.

Fig. 2.—Macropolycyte, Type I, from a case of staphylococcal osteomyelitis.

Fig. 3.—Macropolycyte, Type I, from a case of streptococcal septicemia.

Figs. 4 and 5.—Macropolycytes, Type I, from a case of mixed infection by *Staphylococcus aureus* and *Bacillus coli*.

Fig. 6.—Macropolycyte, Type I, from a case of streptococcal endocarditis.

Fig. 7.—Macropolycyte, Type I, from a case of carcinoma of the breast.

($\times 1,000$ diameter.)

Plate II. Fig. 7 is a macropolyocyte from a case of carcinoma of the breast.

Total leucocytes	14,500 per c.mm.
Polymorphs	76 per cent.
Polynuclear count	35, 36, 26, 2, 0.

It will be seen that the macropolyocytes have hypersegmented nuclei, although polymorphs with single and bilobed nuclei predominate in the blood films, with, in many cases, an occasional myelocyte. What is the explanation of their presence? It is not easy nor particularly important to determine why macropolyocytes appear in health and in infections, because they are rare and do not seem to have any prognostic or diagnostic significance. There are two possible explanations of their presence. The first that they represent an occasional polymorph that has escaped the physiologic mechanism whose function is the destruction of aged leucocytes and their removal from the blood stream. A polymorph has been imprisoned in some tissue space, exceeded its allotted span of life, and continued to develop beyond the normal limits. The result is that it has become a giant. The second explanation is that they are cells whose development has been altered by an abnormal medium to which they have been exposed in the marrow during the first period of their development.

THE MACROPOLYCYTES OF PERNICIOUS ANEMIA

1. The Type I macropolyocyte is frequently found in pernicious anemia, and here again it is necessary to consider the general behavior of the polymorph in this disease. Small forms, micropolyocytes, are often encountered (Fig. 1, Plate III). These cells measure 10 microns or less in diameter, and the nucleus may be single or multilobed. From the micropolyocyte all gradations occur up to the macropolyocyte. As we have seen above in the infective state the polynuclear count is left-handed. Many uncomplicated cases of pernicious anemia, however, show the remarkable state of having an increase in the cells of Classes IV and V, and the count appears to be actually right-handed, as the following figures show:

	I	II	III	IV	V
Normal	10	25	47	16	2
Case 1	8	20	39	22	11
Case 2	6	27	40	22	5
Case 3	7	20	44	24	5
Case 4	7	16	29	39	9
Case 5	20	31	17	10	10
Case 6	16	22	32	16	14
Case 7	10	15	38	24	13
Case 8	12	34	26	20	8
Case 9	6	20	42	20	12
Case 10	8	24	30	26	12
Case 11	6	18	36	24	16
Case 12	6	20	40	26	8
Case 13	14	28	23	20	15
Case 14	12	28	36	18	6

This condition is not seen in any microbial disease.

It has been pointed out above that no class is made in the polynuclear count for cells with more than five lobes in their nuclei, because cells with more

($\times 1,000$ diameters.)

than five lobes are rare in normal blood, and if any are found they are placed in Class V. In pernicious anemia, on the contrary, hypersegmentation of the nucleus in cells of normal size is frequent. The nucleus may have six, seven, eight, or even ten or more divisions. Plate III, Figs. 2 to 8 are examples of this

PLATE IV.

Figs. 1 to 12 illustrate the third type of macropolycyte. The figures show the large bulk of the nucleus, the structure of which appears to be a more open meshwork than normal, suggesting deficiency in basichromatin. The fine cytoplasmic oxyphil granules are also seen. ($\times 1,000$ diameters.)

nuclear hypersegmentation in cells of approximately normal diameter. Plate III, Figs. 9 to 14 are examples of the Type I macropolycyte. Its frequency in pernicious anemia contrasts very sharply with its rarity in health and in infective conditions, and the cause of its appearance is probably not the same.

There are several possible causative factors. Polymorphs of normal size with hypersegmented nuclei accompany the Type I macropolycyte in this disease, and the first thoughts are that there is some biochemical change in the plasma that prematurely ages the polymorph and alters its life history; the second, that the mechanism for the elimination of old polymorphs is in abeyance. The third reasonable hypothesis may be advanced that the polymorph is inherently abnormal owing to a defect in its parent, the hemocytoblast, or in its environment. Possibly, too there is a single biochemical defect that is responsible for all three conditions. The liver diet, or hog's stomach alters the polymorph picture in a few days. Macropolycytes and polymorphs with hypersegmented nuclei disappear, and at the same time the morphologically and probably also chemically abnormal cells of the hemoglobiniferous series are replaced by cells of normal appearance.

2. The Type II macropolycyte is found only in pernicious anemia, and appears in blood films during serious relapses. Almost all the cases in which it has been found have had erythrocyte counts of less than 1,000,000 per c.mm., and before the era of liver treatment all died within a short time of its appearance. After death these large cells are found in the liver and preaortic glands in association with islets of megaloblasts. Plate III, Figs. 15 to 25, illustrates the variations in this type of cell. The cells are large, measuring up to 24 or more microns in diameter, and resemble the megakaryocyte of the marrow.

3. The third type of macropolycyte, illustrated on Plate IV, is also found in pernicious anemia only. Its characteristics have already been described and are seen in the figures. Like the second type it is found in grave relapses and its appearance before the introduction of modern treatment was of grave prognostic import. We believe this cell is a variant of the preceding type and the explanation of its presence in the blood stream to be the same.

These cells do not resemble any embryonic or postnatal blood stream cell, nor are they accurate replicas of the megakaryocyte of the marrow. The life history would appear similar to that of the polymorph in that they seem to commence circulatory existence with a single-lobed nucleus which later becomes segmented. The length of life we do not know, nor have we any means of calculating it. There is considerable doubt about their origin. They may be an expression of the abnormal reversion to embryonic type of the marrow hemocytoblast as are the hemoglobiniferous cells in pernicious anemia. On the other hand, the cells may not arise in the marrow, but originate in the mesenchyme descendants in the liver and hemolymph glands that have undergone abnormal metaplasia.

CONCLUSIONS

1. The macropolycyte found in health and in infections has no diagnostic nor prognostic significance, and is probably due to the accidental prolongation of the lifetime of a neutrophile polymorphonuclear leucocyte.

2. The causation of the appearance of the Type I macropolycyte in pernicious anemia is closely related with the factor responsible for the production

of hypersegmentation in the nuclei of the polymorph. Whether the factor is a biochemical change in the environment or an inherent defect in its parent cell is not known.

3. The Types II and III macropolyocytes may have their origin in the marrow, or may arise from the endothelium of the liver and hemolymph glands. In the first case they are products of abnormal reversion of the hemopoietic tissue, and in the second of abnormal myeloid metaplasia.

Photomicrographs by C. F. Hill and W. E. Cooke.

I most gratefully acknowledge the kind permission of Messrs. Charles Griffin and Co., London, to reproduce Plate I from the Polynuclear Count, Dr. Paul Chevalier, for Plate II from Le Sang, and the Editors of the Journal of the Royal Microscopical Society for Plates III and IV.

SODIUM RICINOLEATE*†

I. AN ATTEMPT TO DETERMINE ITS ACTION IN THE ALIMENTARY TRACT

JOHN T. MYERS, M.D., PH.D., E. L. MACQUIDDY, M.D., AND
 CHARLES P. BAKER, M.D., OMAHA, NEB.

SODIUM ricinoleate, one of the soaps of castor oil, has been and is at the present time, widely used clinically. It appeared to us that an attempt would be desirable to determine the site of its action and the mechanism of its action when used in the intestinal tract.

Two methods were employed in the attempt to elucidate these points. The first was by means of a dye, Sudan IV or azo-orthotoluene-azo-B-naphthol. This dye is soluble in oils, ethers, chloroform, fat, fatty acids, and soaps. It is insoluble in aqueous solutions. Sudan IV was first used by Daddi in 1896 in a study of fat absorption. When a fatty acid in which Sudan IV has been dissolved is saponified, the Sudan IV remains with the fatty acid and the result is a pink soap. Also, if the dye is mixed with the soap and hydrochloric acid added, the Sudan IV will remain with the fatty acid radical. In view of this property of Sudan IV, it would seem to be an acceptable guide as to the route taken by the fatty acid radical during digestion. It was found by Mendel and Daniels (1912) that Sudan IV fed alone caused no staining of the fat depots, hence was not absorbed. This was checked by Gage and Fish

*From the Department of Bacteriology and Pathology and Department of Medicine, University of Nebraska College of Medicine.

Received for publication, March 6, 1933.

†This study was made possible by a grant from The William S. Merrell Company.

(1924) who found that animals fed boiled rice and cooked egg white with which Sudan IV was intimately mixed showed no absorption which they could detect.

The second method of attack was discovered by Edmunds in 1877 and put to use by S. H. Gage in 1924 in his study on the absorption of fats. In this method the minute fat particles (chylomicrons) in the blood were counted. Edmunds said, "If fresh, transparent blood serum with a few corpuscles shaken out of the edge of the clot be viewed, the serum is seen filled with a nebulous haze of points as is mote laden air in a sunbeam or in the electric light." These small particles were counted by means of a net micrometer in the eyepiece of the microscope and a dark-field illuminator. The particles were easily recognized because of their continuous Brownian movement. The technique used was that of Gage and Fish (1924) in which a small drop of blood was placed on a No. 1 cover slip. This was then put on a slide and the excess blood pressed out. The preparation was oiled around the edge of the cover slip to prevent drying.

With these two methods the action of sodium ricinoleate in the intestinal lumen was studied and compared with that of ordinary fats and fatty acids.

The literature on the subject of fat absorption is not in strict accord. Radziejewski (1868) believed that fats were, for the most part, absorbed as soaps. He based this belief on experiments in which he measured the amount of soap fed to animals and the amount excreted in the feces. He believed there was less in the feces, indicating absorption. Plant (1908) isolated loops of small intestine 55 to 75 cm. in length in which he placed fats and soaps. According to his findings, neutral fats were slightly absorbed and soaps in greater quantity. Such a procedure as Plant's would, presumably, alter physiologic relations considerably. Whitehead (1909) believed that fats were absorbed mostly as soaps with probably a small amount taken up as neutral fat. The work of Clark and Clark (1917) indicated that fat could be taken up by the leucocytes and transported to the lymphatics in the unsplit form. Bloor (1916) said, "The way in which food fat (or at least a part of it) gets from the intestine into the blood has been quite satisfactorily determined. It is saponified in the intestine, absorbed in the water soluble form as soaps and glycerol, resynthesized by the intestinal cells and passed into the chyle and thence to the blood as neutral fat (glycerides) suspended in the plasma in a very finely divided condition." Bang (1918) agreed that fats were absorbed as soaps and were changed back to neutral fats in the intestinal wall. Bloor (1922) still believed that fats could be absorbed as soaps but also said that fatty acids and glycerol could be taken up and resynthesized into fats. In 1925 he stated that fatty acids and glycerol were readily absorbed and that in their passage through the intestinal wall they were resynthesized into fats. There was no statement made about the absorption of soaps.

Verzar and Kuthy (1929) advanced another idea as to the method of fat absorption. They showed that oleic, stearic, and palmitic acids would make clear solutions with sodium glycocholate and sodium taurocholate. This would render fatty acids diffusible and so transportable from the intestinal lumen to the blood stream.

Perhaps the most commonly accepted theory at present is that neutral fats enter the small intestine as such, but at this point the reaction becomes alkaline and the lipase breaks the neutral fat into fatty acids and glycerol. The bile aids by breaking the neutral fat into minute particles so that the lipase will have access to the neutral fat more easily. The fat then enters the intestinal wall as fatty acid and glycerol where it is resynthesized into neutral fat, probably by the lipases found in the intestinal cells. At least the fat is in the neutral state by the time the lacteals are reached.

The question still exists as to the possibility of the absorption of fats as soaps. If fats are absorbed as soaps, a soap made from a fatty acid in which Sudan IV is dissolved to identify the fatty acid radical, in case absorption takes place, indicates its eventual deposition by pink fat depots. Also after giving the soap, the chylomicron (fat particle) count should increase, as it does after a fat meal. According to Bloor, Gillette, and James (1927) the chylomicron count, in general, parallels the quantitative determinations of fat in the blood.

In the studies made in this laboratory on the utilization of fats and soaps in the intestinal tract, white rats were used. Whenever possible the animals were not forcibly fed, but in the case of the soaps this was necessary. Here, under ether anesthesia, a small catheter was passed into the stomach and the soaps introduced. Fearing that ether anesthesia might influence absorption, control animals were anesthetized and fed lard. The chylomicron count showed the same increase as in unanesthetized animals. All animals were starved twenty hours before the experiments. There are shown protocols of animals that were fed lard, butter, oleic acid, castor oil and sodium ricinoleate. Soaps were well tolerated when fed by mouth. Intraperitoneal injections of lard, butter, castor oil and sodium ricinoleate were also made in an attempt to determine if absorption from the peritoneum takes place. The following protocols are illustrative of the results obtained.

PROTOCOLS

Rat 1, on June 4, was given ether anesthesia at 9:30 A.M. as a control on its effect in parallel experiments. It was immediately given a meal of toast and lard in which Sudan IV had been dissolved. Chart 1 shows the chylomicron curve during the digestive cycle. The curve is typical and corresponds to those found by Gage and Fish (1924). June 5 and 6 the animal was given stained lard and was chloroformed June 6. The fat of the inguinal, dorsal, omental and kidney regions was stained pink, suggesting good absorption.

Rat 2 was fed soap made from pure lard containing dissolved Sudan IV. A total of 3.1 gm. of soap was fed in 10 per cent solution from May 11 to May 24. The animal remained in good condition throughout and ate corn and oats freely. May 24 the animal was chloroformed. The fat in the depots and in the omentum was not stained. There was some pink material in the stomach. No evidence of absorption was seen.

Rat 3, May 25 at 11:00 A.M. was fed toast spread with butter in which enough Sudan IV had been dissolved to give the butter a distinct red color. This was eaten freely. May 26 at 11:45 A.M. the animal was again fed colored butter on toast and ate freely. At 3:15 P.M. it was chloroformed. The fat of the mesentery, of the other depots, and around the kidneys was decidedly pink in color which indicated good absorption of the butter.

Rat 4 was fed oleic acid stained with Sudan IV. The chylomicron count was made twenty-four hours later and the results are shown in Chart 2. On each of the two following days the animal was fed 1 c.c. of the stained fatty acid. Four hours following the last feeding the animal was chloroformed. The omental and perirenal fat was stained deeply pink. The fat depots of the groin and back were well stained, and there was some pink fat all through the small intestine. Oleic acid was quite irritating and produced some diarrhea, pink material appearing in the stools. Despite this, there is evidence that oleic acid is absorbed.

Rat 5. Oleic acid containing dissolved Sudan IV was saponified and 1 c.c. of an 18 per cent sodium oleate solution fed daily for four consecutive days. The results of the chylomicron count are shown in Chart 3. On two succeeding days the animal was fed 1 c.c. of the soap and chloroformed four hours after the last feeding. None of the fat depots were stained, although an abundance of pink material remained throughout the lumen of the small intestine. The chylomicron count indicates that there was no fat absorption, as does the absence of stained fat.

Chart 1.—Rat 1, chylomicron curve.

Chart 2.—Rat 4, chylomicron curve.

Chart 3.—Rat 5, chylomicron curve.

Rat 6, at 8:00 A.M., was fed toast spread with castor oil in which Sudan IV had been dissolved. Twenty-four hours later it was again fed toast and dyed castor oil and was chloroformed at 1:30 P.M. There was pink material in the stomach and small intestine but none in the colon. No staining of the fat in the mesentery, around the kidneys or in the fat depots in the inguinal or back region was seen, indicating lack of absorption.

Rat 7 was fed 0.23 gm. of sodium ricinoleate in which Sudan IV had been dissolved. The soap was fed as a 10 per cent aqueous solution which formed a clear, transparent pink liquid. The initial dose was given May 9, 1932, and repeated daily until 3 gm. had been fed. May 24 the animal was chloroformed and examined. The fat depots, including the omental fat, were not stained. There was pink material in the stomach and small intestine, but none in the colon. The animal had been given a basic diet of corn and oats and was in good condition at the time of death. There was no evidence of absorption.

Rat 8 was fed 4.3 gm. of sodium ricinoleate in 25 per cent solution from May 21 to May 30, when he died of multiple lung abscesses. There was no staining of the mesentery,

perirenal fat or fat in other depots. The administration of sodium ricinoleate probably had nothing to do with the lung condition.

Rat 9, at 10:00 A.M. was fed 0.2 gm. of sodium ricinoleate by means of a tube, under ether anesthesia. Chart 4 shows the curve of the chylomicron count, the count being plotted on the ordinate and the time on the abscissas. There was no evidence of absorption.

Rat 10 was injected intraperitoneally with 3 c.c. of stained 10 per cent lard soap. Three days later the animal was chloroformed and examined. The perirenal, omental and mesenteric fat appeared pink on the surface, but on cutting there was no penetration of stain into the fat. The fat depot of the dorsal region was unstained. No evidence of absorption was seen.

Rat 11 was injected intraperitoneally with 1 c.c. of butter stained with Sudan IV and the injection repeated the following day. Two days later the animal was chloroformed. There was no staining in any region, including the back, groin, kidney, mesentery, and omentum. The butter and Sudan IV remained in the peritoneal cavity.

Rat 12 was injected intraperitoneally with 1 c.c. of castor oil in which Sudan IV had been dissolved, and this was repeated the following day. Two days later the animal was chloroformed. The material injected still remained in the peritoneal cavity. The omental, perirenal, inguinal and dorsal fat was perfectly white and showed no staining.

Rat 13 was injected intraperitoneally with 3 c.c. of stained 20 per cent sodium ricinoleate and died in three hours. There was no recognizable staining of any body fat. There was

Chart 4.—Rat 9, chylomicron curve.

serous, blood-stained fluid in the peritoneal cavity and the peritoneum was inflamed, but this action is not considered specific for sodium ricinoleate.

There was also noted a very marked increase in the erythrocyte count. We make no explanation of this fact, but did note that 2 c.c. of a 10 per cent silver nitrate solution or 2 c.c. of 2½ per cent nitric acid injected intraperitoneally produced the same results.

Rat 14 at 9:15 A.M., was given 2 c.c. of stained 10 per cent sodium ricinoleate, intraperitoneally. At the time of injection the erythrocyte count was 7,960,000 and at 10:05 the count had risen to 8,200,000. The animal died before another count was made. Examination showed no evidence of fat staining, and there was some fluid in the peritoneal cavity but no more than was injected.

Rat 15, at 10:50 A.M., was injected intraperitoneally with 2 c.c. of stained 5 per cent sodium ricinoleate. Examination showed a small amount of blood in the pleural cavities. There was some soapy material in the peritoneal cavity but no more than was injected, and the peritoneum was inflamed. There was no evidence of staining of the fat in any region. Table I shows the erythrocyte count, white cell count and chylomicron count.

From the above work, based on the study of fat absorption and deposition by the use of Sudan IV and chylomicron counts, it would appear:

1. That the neutral fats, butter, lard, and free oleic acid, are absorbed from the intestinal canal.
2. That the neutral fat, castor oil, is not so absorbed.

3. That soaps made from lard, butter or castor oil (sodium ricinoleate) were not thus absorbed.

4. That none of the above substances were absorbed from the peritoneal cavity.

TABLE I

RAT 15

TIME	ERYTHROCYTE COUNT	WHITE CELL COUNT	CHYLOMICRON COUNT
10:50 A.M.	8,130,000	8,400	90
11:50	9,500,000	5,700	7.5
1:10 P.M.	10,040,000		9
2:20	10,510,000		15
3:00	Animal died		

DISCUSSION AND SUMMARY OF PROTOCOLS

The evidence here presented indicates that soaps are not absorbed from the alimentary tract. This is in direct contradiction to the conclusions of earlier workers who believed that fats are absorbed as soaps, even though a soap splitting enzyme has never been isolated. This work suggests that fats are absorbed as fatty acids and glycerol. We cannot explain the lack of absorption of castor oil. Gage and Fish (1924) also found that it was not digested. They suggested, as a possible explanation, the fact that ricinoleic acid contains more oxygen than do the ordinary fatty acids which are readily absorbed. Perhaps the same explanation may be applied to the soap as to the oil, but, since ordinary fat soaps are not absorbed, this appears to be a question of the soap group rather than of a specific soap.

The results with intraperitoneal injection of lard, butter, sodium ricinoleate and castor oil stained with Sudan IV indicated that these fats and soaps are not absorbed by the peritoneal surface. Castor oil was perfectly innocuous in the peritoneal cavity, in marked contrast to the castor oil soap.

Sodium ricinoleate is apparently not absorbed by the intestinal mucosa, hence any action it may exert should be limited to the lumen of the intestinal canal.

SUMMARY

1. The evidence indicates that oleic acid, butter, and lard are absorbed from the intestinal canal.
2. There is no evidence that soaps or castor oil are absorbed from the intestinal canal.
3. By the methods thus employed, butter, lard, lard soaps, castor oil, and sodium ricinoleate are not absorbed from the peritoneal cavity. Sodium ricinoleate appeared toxic in high concentration.
4. Any action of sodium ricinoleate administered orally would seem to be limited to the intestinal canal. Work is being continued in an effort to identify such action.
5. If the deaths of Rats 13 and 14 and the irritation in Rat 15 are an indication of absorption, we believe it is absorption of a material other than

the fatty acid radical stained with Sudan IV. No attempt to find other methods of absorption was made.

SODIUM RICINOLEATE*†

II. A STUDY OF THE INTESTINAL FLORA DURING ORAL ADMINISTRATION

JOHN T. MYERS, M.D., PH.D., E. L. MACQUIDDY, M.D., AND
 CHARLES P. BAKER, M.D., OMAHA, NEB.

SODIUM ricinoleate is used in gastrointestinal disorders which are believed to be due to a disturbance within the tract itself. To what extent these various disturbances are due to intestinal flora or to products of digestion is not known. This paper is a study of the effect of sodium ricinoleate, administered by mouth, on the intestinal flora.

Sodium ricinoleate was probably first used in bacteriologic work by Larson, Cantwell and Hartzell in 1919. They found a solution of sodium ricinoleate very effective in lowering the surface tension of media, by which the growth of bacteria was greatly influenced.

Albus and Holm (1926) reported that when the surface tension of the medium was lowered to forty dynes by means of sodium ricinoleate, the growth of *Lactobacillus bulgaricus* was inhibited, while *Lactobacillus acidophilus* grew well at thirty-six dynes.

*From the Department of Bacteriology and Pathology and Department of Medicine University of Nebraska College of Medicine.

Received for publication, March 6, 1933.

†This study was made possible by a grant from The William S. Merrell Company.

M. Frobisher (1926) found that surface tension is an important factor in bacterial growth. He used sodium oleate as a depressant but not sodium ricinoleate. W. R. Albus (1927), using sodium ricinoleate as a surface tension depressant, found that there was a decrease in the number of living cells in cultures of *E. coli*.

Pizarro (1927) found that inhibition of bacterial growth was not directly associated with surface tension. In many instances the greatest inhibition occurred at higher surface tensions, while broth at lowest surface tension gave the maximum development. This indicates that inhibition is due to the chemical nature of the depressant rather than lowering of surface tension. Day and Gibbs (1928) show that sodium ricinoleate is more toxic to bacteria than other soaps. They found that it is not the depression of the surface tension which affects the bacteria but some other action, possibly chemical. They reported that sodium ricinoleate exerted a more toxic action toward *L. acidophilus* than toward *L. bulgaricus*.

Kozlowski (1928) found that sodium ricinoleate in a dilution of 1:5,000 killed streptococci isolated from cases of erysipelas, measles, and scarlet fever in about seven hours, while control cultures survived for a week or more. Growth was inhibited by a dilution of 1:20,000 or less. Pneumococci were dissolved by a dilution of 1:5,000. *C. diphtheria* was inhibited by a dilution of 1:20,000 and killed by a dilution of 1:2,000 in seven hours. *S. paratyphosus*, *E. dysenteriae*, *E. coli*, and *Strep. fecalis* were very resistant to the bactericidal and inhibitory action of sodium ricinoleate. He concluded that specific cellular susceptibility of the bacteria and the concentration of the soap affects its bactericidal and inhibitory action.

Walker (1924) found the staphylococcus had a marked resistance to soaps in general. He found that the laurates had the greatest germicidal action of any soap. Pneumococci and streptococci were the most readily affected. He did not use sodium ricinoleate.

Spencer (1930) found that sodium ricinoleate, in appropriate amounts, completely cleared suspensions of certain species in normal salt solution, notably *B. tularensis*. He found that the density of suspensions of some other bacteria was increased by the addition of sodium ricinoleate and in still others the density would be increased at one dilution and decreased at another. He noted that many bacteria would grow in a 1 per cent solution of sodium ricinoleate. Upon observing the action of sodium ricinoleate upon *B. tularensis* with the dark-field illuminator, he found that the individual cells lose their refractility as a whole, but retain a few refractile granules for a time, which finally disappear, the resulting solution being noninfectious for guinea pigs.

The literature leaves undetermined the mode of action of sodium ricinoleate. There is no doubt that it has some effect upon bacteria but the mechanism is not clear. Apparently surface tension is not the only factor involved.

Selecting one of the most common members of the intestinal flora, *E. coli*, the percentage of sodium ricinoleate necessary to inhibit growth in cultures was studied. Plain broth was selected as one medium and a filtrate from stools of patients as another. The latter was chosen because conditions as

nearly as possible like those in the intestine were desired. Sodium ricinoleate was added to the media in varying amounts. The tubes were inoculated with a strain of *E. coli* isolated from a human source and incubated at 37° C. for twenty-four hours. Then a loopful was spread on a blood agar plate and incubated for twenty-four hours. Tubes which contained no sodium ricinoleate were used as controls. Tables I, II and III give the results:

Table I demonstrates that at least a 7 per cent solution of sodium ricinoleate is required to completely inhibit the growth of *E. coli* in plain bouillon. In filtrate Tubes 2, Table II, there was no growth in any dilution nor in the controls. In two series of tubes in which nutrient broth was added to filtrate, the growth was inhibited by a 5 per cent solution of sodium ricinoleate while in a fourth series the organisms grew in every dilution. In Table III growth was inhibited in a 4.1 per cent solution in two series of tubes and in two others there was no inhibition in any dilution including the 8.3 per cent sodium ricinoleate. Thus, *E. coli* was quite resistant to the action of sodium ricinoleate, as far as growth is concerned.

The tubes in which there was growth in every dilution were found to have a white precipitate in the bottom resembling a calcium soap. These filtrates were found to contain considerable free calcium by quantitative test. The stools of ten patients who were receiving sodium ricinoleate by mouth were tested qualitatively for calcium, and it was found to be present in all, although in some in small amounts only. This suggests the possibility of sodium ricinoleate being sometimes precipitated as the insoluble calcium salt and rendered inactive when the drug is given by mouth and might indicate the use of much larger therapeutic doses.

In Part I of these papers it was found that the soap is apparently not absorbed from the intestinal tract. It would therefore appear that any action which the drug possesses must be local, and an attempt has been made to ascertain whether any local action can be detected by changes in the intestinal flora. In this, the effect of sodium ricinoleate on the general intestinal flora was studied by direct smear and by cultures. Cultures were made on blood agar plates, in brain broth and in cooked heart medium because each favors a different type of microorganism. No attempt was made to isolate and identify every variety because of the volume of work which would be entailed by such a procedure.

Sodium ricinoleate was administered orally in 5 or 10 gr. gelatin coated capsules. Thirty to 40 grains were given daily to each adult patient. The capsules were given thirty minutes before each meal and at bedtime, as the drug was better tolerated when the stomach was empty.

A specimen of stool was obtained from each patient before sodium ricinoleate was administered and as nearly as possible weekly thereafter. No stool more than five hours old was used. All glassware was autoclaved. Approximately 1 gm. of material from the center of the stool was emulsified with 75 c.c. of sterile isotonic sodium chloride solution. The emulsion was poured into an Erlenmeyer flask, shaken for one and one-half minutes, and centrifuged for thirty seconds at half speed, which was sufficient to throw coarse material down, but left bacteria in suspension. From this suspension, media were inoculated and slides made and stained by Gram's method. The P_H of each stool was determined by the colorimetric technic, using brom-thymol-blue as an indicator. For stools which were more acid, brom-cresol-purple was used. Sodium ricinoleate by mouth apparently did not influence the P_H of the stools. The patients were treated for eight weeks or longer. The direct smears from the stools were stained by Gram's method. Gram stains were made from the brain broth and heart media and from all varieties of colony on blood agar plates after forty-eight hours' incubation at 37° C. This was done prior to beginning the administration of sodium ricinoleate and each week thereafter.

Ten patients were studied in this manner and protocols kept. Table IV is a reproduction of one such protocol. It is considered unnecessary to include the others because, while there were minor variations, the general trends were the same.

Patient was given forty grains sodium ricinoleate daily for sixty-four days					

SUMMARY

The daily administration of 30 to 40 gr. of sodium ricinoleate by mouth for about eight weeks had no evident effect on the character of intestinal flora as far as was indicated by direct smear and the cultural characteristics observed. All types of bacteria grew as readily during the administration of sodium ricinoleate as before. The ratio of gram-negative to gram-positive organisms was not changed. In these patients every stool seemed to contain 90 per cent or more of gram-negative bacteria, and these were largely colon bacilli. The growth of all organisms in the media employed seemed just as prolific during the administration of sodium ricinoleate as when no medication was given. The P_H of the stools was not appreciably altered by sodium ricinoleate. Larger doses of sodium ricinoleate might be more effective, for some of the drug appears to be precipitated by the calcium in the intestinal

contents. This would be especially true in those cases where the P_H was quite low. That this could be done with impunity is indicated by the fact that doses which were comparatively several times larger were given to white rats for weeks with no ill effects. For instance, one gram was given daily to one rat through a stomach tube, and at no time did it affect its appetite or well-being.

CONCLUSIONS

1. *E. coli* was inhibited by 7 per cent sodium ricinoleate in broth culture.
2. Sodium ricinoleate, in the accepted clinical dosage, does not alter the intestinal flora as far as can be detected by direct smears and cultures in the three media employed.
3. Sodium ricinoleate in like dosage by mouth has no demonstrable effect on the P_H of the stool.
4. The gram-negative gram-positive ratio is apparently not changed by sodium ricinoleate.
5. The precipitation of sodium ricinoleate by calcium in the intestinal canal is worthy of study, as larger doses might be needed to replace that lost in this way.

THE VARIATIONS OF THE UREA, TOTAL NONPROTEIN NITROGEN, AND CHLORIDE CONCENTRATION IN THE BLOOD FOLLOWING GLUCOSE INGESTION*

MAURICE BRUGER, M.D., M.Sc.,† AND I. ARTHUR MIRSKY, M.D., M.Sc.,†
NEW YORK, N. Y.

WITH THE TECHNICAL ASSISTANCE OF
SAMUEL MEMBER, B.S.

HERRICK¹ and Katayama² observed a fall in the chloride content of whole blood following the ingestion of glucose in human subjects. An inverse relationship between the concentration of glucose and chlorides in the blood has also been noted in diabetes mellitus by Gram³ and McLean,⁴ also by Myers.⁵ In cases of Bright's disease, Gram⁶ has shown that the retention of nonprotein nitrogenous bodies is often accompanied by a reduction in the chloride content and conductivity of the blood. As in diabetes mellitus with high blood sugar, he assumes that the decrease in conductivity (i.e., salts) represents a regulatory process, which tends to stabilize the osmotic pressure of the blood. McLean⁶ has observed that there is a progressive diminution in the plasma chlorides in some patients with Bright's disease up to the time of death in uremic coma, and the presumption has been made by others that this decrease may be partly explained as an attempt to maintain an osmotic balance in the face of a rise of the nonprotein nitrogenous substances in the blood. Experiments reported by Ni⁷ show that the fall and rise of blood chlorides which occur in pancreatectomized or normal dogs after the injection of insulin are related to the sugar fluctuations, and he assumes such reciprocal changes to be an effort on the part of the body at osmotic and other compensations.

Such compensatory relationships are not uniformly observed during hyperglycemia and nitrogen retention and, as we shall attempt to show later, following the ingestion of glucose in normal and diabetic subjects. Mosenthal⁸ has recently demonstrated that the plasma cholesterol following glucose ingestion may either rise or fall markedly as the blood sugar increases, and consequently the assumption that a reciprocal variation of these two substances maintains the osmotic equilibrium of the blood does not suffice as an explanation for all changes. Experiments carried out in this laboratory on the variations of the plasma proteins during induced hyperglycemia (to be published later) show that the protein fractions of the blood may either rise or fall considerably under such circumstances. It is conceivable when reciprocal relationships between certain constituents in the blood were not observed, that other substances, the

concentrations of which were not investigated, may have varied in such a way as to maintain a constant osmotic pressure of the blood.

MATERIAL AND METHODS

Sixty glucose tolerance tests were carried out in 54 unselected subjects. The variations of the sugar, urea nitrogen, total nonprotein nitrogen and chloride concentrations in the blood were followed at intervals, in most cases, of twenty minutes, forty minutes, one hour, two hours, and three hours following the ingestion of 100 gm. of glucose. The test was carried out in every instance in the morning, the subject having taken no food since the evening preceding the test. The volume output and the sugar content of the urine were also noted. The blood sugar was determined in every case and the patient's tolerance for ingested carbohydrate interpreted according to the standards proposed by Mosenthal.⁹ The variations of the urea nitrogen concentration in the blood were followed in 45 cases, the total nonprotein nitrogen in 13, the whole blood chlorides in 17 and the plasma chlorides in 6.

The methods employed were as follows: urea nitrogen, gasometric urease method of Van Slyke;¹⁰ total nonprotein nitrogen, Folin and Wu;¹¹ sugar, Folin and Wu;¹² whole blood and plasma chlorides, Short and Gellis.¹³

RESULTS

Urea Nitrogen.—Table I illustrates the variations of the urea nitrogen content of the blood in 45 subjects following glucose ingestion. Assuming deviations of ± 1.0 mg. per cent or more of urea nitrogen as significant, the following findings are demonstrated: *Progressive Fall*: (22 instances) Cases 5 to 8, 10, 13, 15, 17, 19, 22, 24, 25, 27, 30, 32 to 34, 37, 39, 41, 43, and 44. *Preliminary Rise and Later Fall*: (12 instances) Cases 2, 4, 11, 16, 20, 26, 28, 31, 35, 38, 40, and 42. *No Significant Change*: (6 instances) Cases 1, 9, 12, 21, 29, and 36. *Progressive Rise*: (4 instances) Cases 14, 18, 23, and 45. *Preliminary Fall and Later Rise*: (1 instance) Case 3.

Apparently, there is no constant reciprocal relationship between the urea and sugar content of the blood. Cases 5 to 8 and 10 show a persistent diminution in the urea nitrogen while the blood sugar has returned to the control level (normal sugar curves). Again, in Cases 31, 35, 38, 40, and 42 an initial rise and later fall in the urea nitrogen are associated with a persistently elevated blood sugar (high prolonged sugar curves).

A marked fall in the urea nitrogen content of the blood (3 mg. per cent or more) is observed in only one out of eleven subjects (9 per cent) with normal carbohydrate tolerance (Case 5). On the other hand, in the 25 subjects with definitely diminished sugar tolerance (high prolonged sugar curves), we record six (24 per cent) such instances (Cases 24, 27, 32, 37, 43, and 44). Two cases in each group show an increment of 3 mg. per cent or more in the urea nitrogen (Cases 3, 4 and 40, 45, respectively).

Our results demonstrate that following the ingestion of glucose the urea nitrogen content of the blood may rise or (and) fall or show no marked change. A diminution of 1 to 7 mg. per cent, however, occurs in about 50 per cent of the cases, and evidence is presented that an appreciable fall (3 mg. per cent or

*Calculated from the total urine volume output following the glucose ingestion until the termination of the test.

Total Nonprotein Nitrogen.—Table II illustrates the variations of the total nonprotein nitrogen content of the blood and the sum total of the nonprotein nitrogenous substances excluding urea in thirteen subjects following glucose ingestion. The following findings are demonstrated:

1. The total nonprotein nitrogen may rise or (and) fall or remain unchanged.

2. The total nonprotein nitrogen shows a progressive fall in many instances and is paralleled by the variations of the urea nitrogen in Cases 6, 22, 26, 30, and 37. In these instances, the diminution in the total nonprotein nitrogen is due mainly to the decrease in the urea nitrogen fraction.

3. The sum total of uric acid, creatinine, amino acid, and rest nitrogen may either rise or (and) fall or show no marked change.

Whole Blood and Plasma Chlorides.—Table III shows the variations of the whole blood and plasma chlorides in seventeen and six cases respectively following the ingestion of glucose. In the six instances with plasma chloride studies, simultaneous determinations of the whole blood chlorides were made. The following findings are demonstrated:

1. A reciprocal relationship between the whole blood chlorides and sugar in Cases 46, 48, 50, 32, 52, 53, 55, and 56. In the first three cases, the fall and subsequent rise in the chlorides are associated with an increase of the blood sugar and a later return to the control level (normal and high sugar curves). In the latter five instances, the persistent diminution in the chloride accompanies a prolonged elevation of the blood sugar (high prolonged sugar curves).

2. Nine subjects show either no change or an augmentation of the whole blood chlorides.

3. The variations of the plasma chlorides parallel the whole blood chlorides in Cases 52, 55, and 56. In Cases 47, 48, and 49, the changes in the blood chlorides are due mainly to variations of the chloride content of the plasma.

DISCUSSION

In 1916, Hiller and Mosenthal¹⁴ showed that the ingestion of 100 gm. of glucose by normal individuals was not accompanied by hydremic plethora. We carried out hematocrit studies in a few instances, and we were able to satisfy ourselves that little if any blood dilution occurred. In fact, we observed a slight degree of blood concentration following glucose administration in some cases. The variations of the constituents investigated, therefore, cannot be explained by changes which develop in the water content of the blood caused by the ingestion of 100 gm. of glucose dissolved in approximately 250 c.c. of water.

If the variations of the urea and other nonprotein nitrogen fractions of the blood and of chloride, plasma proteins, cholesterol, etc., following glucose ingestion represent attempts on the part of the organism to maintain a normal osmotic pressure of the blood, then it becomes clear why one constituent (e.g., urea) may rise, fall, or remain unchanged while another substance or substances (e.g., chloride, cholesterol, etc.) may vary in such a way that the summation of their individual osmotic effects is constant. It is conceivable that the regulation is a property residing in all the body tissues and maintained by an interplay of the electrolytes and nonelectrolytes in tissue fluid and blood.

*Calculated from the total urine volume output following the glucose ingestion until the termination of the test.

No apparent relationship was observed between the degree of diuretic response to glucose and the variations of the several constituents in the blood. Urea, as a nonthreshold body, is capable of a "washing-out" process, but Mosenthal and one of us¹⁵ have shown that a marked degree of diuresis in human subjects does not influence materially the amount of urea cleared by the kidney in a unit of time. Obviously, the large amount of urea in tissues and blood is not affected appreciably by the increased rate of urine excretion. The interesting observation was made that diuresis following glucose administration occurred more often and was more marked in subjects exhibiting normal sugar tolerance than in those with diminished tolerance for carbohydrate. As a rule, mild and severe diabetics are dehydrated to a greater or lesser extent and for this reason it is probable that glucose ingestion in these cases is less apt to produce diuresis.

SUMMARY

The ingestion of 100 gm. of glucose by fasting subjects produced the following effects: (A) The urea nitrogen content of the blood may rise or (and) fall or remain unchanged. A gradual fall in the urea nitrogen (1 to 7 mg. per cent) was observed in 22 out of 45 cases. A definite decrease (3 mg. per cent or more) occurred more often in subjects with diminished carbohydrate tolerance than in those with normal tolerance. (B) The total nonprotein nitrogen of the blood may rise or (and) fall or show no marked change. In many cases, though not in all, the variations in the total nonprotein nitrogen were due mainly to changes in the urea nitrogen fraction. Irregular changes were noted in some instances in the sum total of the nonprotein nitrogenous substances in the blood other than urea. (C) There was a distinct reciprocal relationship between the whole blood and plasma chlorides and the glucose concentration in the blood in many instances, though this was not observed in all the cases studied.

There was no apparent relationship between the degree of diuretic response to glucose and the variations in the constituents investigated. Diuresis following glucose ingestion occurred more frequently and was more marked in subjects with normal carbohydrate tolerance than in those exhibiting a diminished tolerance for sugar.

The hypothesis is suggested that these fluctuations represent an effort by the body to maintain a constant osmotic pressure of the blood. The compensatory response of urea, total nonprotein nitrogen, and chloride to a rise of glucose in the blood is not a uniform reciprocal relation. The varied increase or decrease of these substances suggest that the total osmotic pressure is adjusted according to the physiologic reserve prevailing in the body at a given moment.

THE PERENNIAL TREATMENT OF HAY FEVER*

A COMPARATIVE STUDY

ABRAHAM COLMES, M.D., BOSTON, MASS.

IN 1911, Noon¹ and Freeman² introduced the method of preseasonal desensitization of hay fever with specific pollen extracts. Their technic consisted of the subcutaneous inoculation into a sensitive patient of a number of increasingly potent pollen doses during the course of from ten to fifteen weeks preceding the date of expected pollination. While the merits of this treatment have since been generally recognized, the efficacy of their technic has been marred by the following objections: the inconvenience caused to the patient by the necessity of frequent visits to the office or clinic throughout the treatment period; the occasional need of a longer treatment period than allotted, in refractory cases; and finally, the rapid loss of the patient's acquired tolerance for pollens in the interim between treatment seasons.

In 1926 Zella W. Stewart³ suggested the "throughout the year treatment of hay fever," which, she claimed, met the above-mentioned objections effectively. By this method the patient is reinjected with an optimal dose of pollen extract at intervals of from two to four weeks throughout the year, thus maintaining his acquired immunity. In 1927 and again in 1932 Aaron Brown,⁴ working independently, described the "perennial" treatment of hay fever, for which he claimed similarly favorable results.

Additional observations on the perennial method of pollen therapy have since been made by Vander Veer, Cooke and Spain,⁵ Figley,⁶ Thommen,⁷ Vaughan,⁸ and Unger.⁹ In their final analysis these authors subscribed to all or most of the following advantages of the perennial over the preseasonal

*From the Anaphylactic Clinic of the Beth Israel Hospital, and the Anaphylactic Clinic of the Massachusetts General Hospital.
Received for publication, March 8, 1933.

method of hay fever treatment: fewer office visits, better clinical end-results, greater convenience to the patient, and the possibility of permanent cures. They varied, however, on the incidence of constitutional reactions, which occurred more frequently by the perennial method in the series of Vander Veer, Cooke and Spain, and Thommen, as against a lesser incidence of similar reactions in the series of Figley, Vaughan, and Unger.

The magnitude of the problem of hay fever and the desire to elucidate further the merits of this innovation in its treatment prompted the undertaking of the study set forth in this communication.

Altogether 52 patients were treated by the perennial method during the year ending October, 1932. Of these, 34 patients had formerly received pre-seasonal treatment for one or more years and form the basis for comparing these two methods on the same group of patients in different years. At the same time 46 other patients who received preseasonal treatment in 1932 serve as additional material for comparing the perennial and preseasonal methods of treatment during the same season, though on different patients.

In Tables I, II, III, and IV, the results of our observations are tabulated under corresponding headings. It is evident that "complete relief" was about

TABLE I

A COMPARISON OF THE END-RESULTS IN 34 HAY FEVER PATIENTS TREATED PERENNIALLY IN 1932 AND PRESEASONALLY IN 1931

	1932 PERENNIAL	1931 PRESEASONAL
Complete relief	24 per cent	12 per cent
Marked relief	67 per cent	76 per cent
Slight relief	6 per cent	12 per cent
No relief	3 per cent	-----
Total per cent of good results	91 per cent	88 per cent

TABLE II

A COMPARISON OF THE AVERAGE NUMBER OF DOSES, AVERAGE AMOUNT OF POLLEN IN 1-100 DILUTION AND OF THE INCIDENCE OF CONSTITUTIONAL REACTIONS IN 34 HAY FEVER PATIENTS TREATED PERENNIALLY IN 1932 AND PRESEASONALLY IN 1931

	1932 PERENNIAL	1931 PRESEASONAL
Average number of doses	22	19
Average amount of pollen in 1-100 dilution	5.60 c.c.	2.04 c.c.
Constitutional reactions	0.06 per cent (1 reaction in 152 treatments)	0.07 per cent (1 reaction in 131 treatments)

TABLE III

A COMPARISON OF THE END-RESULTS OF HAY FEVER TREATMENT BETWEEN 52 PERENNIAL AND 45 PRESEASONAL CASES IN 1932

	PERENNIAL	PRESEASONAL
Complete relief	21 per cent	13 per cent
Marked relief	73 per cent	71 per cent
Slight relief	4 per cent	13 per cent
No relief	2 per cent	3 per cent
Total per cent of good results	94 per cent	84 per cent

TABLE IV

A COMPARISON OF THE AVERAGE NUMBER OF DOSES, AVERAGE AMOUNT OF POLLEN IN 1-100 DILUTION AND OF THE INCIDENCE OF CONSTITUTIONAL REACTIONS IN 52 PERENNIAL AND 45 PRESEASONAL CASES IN 1932

	PERENNIAL	PRESEASONAL
Average number of doses	24	21
Average amount of pollen in 1-100 dilution	5.89 c.c.	2.62 c.c.
Constitutional reactions	0.06 per cent (1 reaction in 156 treatments)	0.04 per cent (1 reaction in 236 treatments)

twice as frequent with the perennial method as compared with the preseasonal in both groups, while the instances of "slight relief" and "no relief" were more common in the preseasonal group. The amount of "marked relief," however, which the bulk of the patients experienced, was not appreciably different in the two groups. Altogether the group of 34 patients who were treated preseasonally in 1931 and perennially in 1932 obtained 88 and 91 per cent of good results in the respective years, while the other two groups, one of 45 preseasonal cases and the other of 52 perennial cases treated in 1932 experienced 84 and 94 per cent of good results respectively. For the slightly better total good results in the perennially treated cases, each patient received an average of three more doses and a total of about twice as much pollen as the preseasonally treated patients.

As seen from our tables, constitutional reactions occurred with slightly greater frequency in the 52 patients treated perennially in 1932 and in the 34 patients treated preseasonally in 1931. It is well to mention here that altogether we had 3 constitutional reactions which required adrenalin. Two of these occurred in perennially treated patients and one in a preseasonal patient. All other reactions were mild and needed no special medication.

TABLE V

ELEVEN CASES WHO OBTAINED BETTER RELIEF IN 1932 BY THE PERENNIAL METHOD

	1931 PRESEASONAL	1932 PERENNIAL
11 Cases	4 patients, slight relief 7 patients, marked relief	Marked relief Complete relief

FOUR CASES WHO OBTAINED WORSE RESULTS IN 1932 BY THE PERENNIAL METHOD

	1931 PRESEASONAL	1932 PERENNIAL
4 Cases	1 patient, complete relief 2 patients, complete relief 1 patient, marked relief	No relief Marked relief Slight relief

Of considerable interest is a group of 11 patients who obtained better relief in 1932 when treated by the perennial method than in 1931 when treated preseasonally. Against these we have 4 patients whose results in 1932 were inferior to those in 1931.

We were unable to standardize the time interval between treatments in the perennial group due to variation in changes in the individual patient's tolerance for pollen as determined by repeated serial skin tests and by the

extent of the local reactions from the previous dose. Most patients were treated at three-week intervals, some at four-week intervals, while a few patients could not maintain their tolerance any longer than two weeks. Two patients who had been refractory to treatment in the past received inoculations practically every week with excellent therapeutic results. In addition all patients were given weekly treatments throughout the pollinating season.

COMMENT

It is evident from this study that the perennial method of pollen therapy which is gaining considerable impetus in its clinical application is not infallible. While it offers a somewhat higher total of "good results" from treatment, it proved inadequate in about 12 per cent of our patients who had better relief when treated by the preseasonal method. Furthermore, in our series, the perennial method necessitated a larger number of visits per patient, and it showed no diminution in the incidence of constitutional reactions as compared with the preseasonal method. The one factor that seems to be decidedly in favor of the perennial method is the time element which permits of sufficient treatment in the refractory type of patient as evidenced by two of our cases who required inoculations at weekly intervals, throughout the year.

Of additional interest is the patient's personal reaction to this newer method of treatment. Those who could tolerate treatment at four-week intervals did not mind the occasional visits, while others who had to come in once every two weeks, resented the thought of the "endless visits to the doctor." They felt that eight or even seven months of freedom from treatment was a desirable period for relaxation.

Particularly unpleasant were those few instances when patients, though satisfied with the preseasonal method, acceded on our advice to the more trying perennial method, only to find the end-results less satisfactory. A case in point is the following: F. V. had complete relief in 1929, 1930, and 1931 by the preseasonal method of treatment, while in 1932, by the perennial method, his relief was only partial, although his maximum dose was the same each year. It is apparent that the frequency of administration of pollen doses may in certain instances influence the end-results in therapy.

As to the possibility of permanent cures by the perennial method, we cannot voice any opinion, since this study is based on the experience of one year's treatment. Should the permanent results ultimately prove to be better, one may disregard the several disadvantages incidental to the perennial method of treatment and advocate it with fewer reservations. For the present, however, we must accept this method only as "another method" applicable in selected cases, the most important indication for its use being refractoriness to treatment, where the time element is concerned.

Sight must not be lost of those instances pointed out by Rackemann,¹⁰ whose treatment by the preseasonal method may be reduced to six or even three doses a year, which is an impossibility by the perennial method in the best of hands.

Finally, a great many pollen sensitive patients are treated by the practitioner who may find the perennial method more complicated and less safe to the patient than the more simple preseasonal method of desensitization.

SUMMARY

A comparative study of the perennial and preseasonal methods of hay fever therapy indicate that:

1. The total good results from treatment were somewhat higher by the perennial method.
2. In about 12 per cent of the cases the results obtained by the perennial method were inferior to those produced by the preseasonal method of treatment.
3. The number of treatments per patient were greater by the perennial method.
4. Constitutional reactions occurred with slightly greater frequency in the perennially treated group.
5. The technic of treatment is far more complicated by the perennial method, while the convenience to the patient seems greater when treated by the preseasonal method.

Dr. Francis M. Rackemann's critical review of this manuscript is hereby gratefully acknowledged.

REFLEX EOSINOPHILIA*

FELIX P. CHILLINGWORTH, M.D., JAMES C. HEALY, M.D., AND
FRANK E. HASKINS, M.D., BOSTON, MASS.

SEVERAL years ago one of us† produced emphysema with accompanying asthmatic syndrome in dogs by means of an intratracheal ball valve. Briefly, this condition was induced by the introduction of a ball valve into the trachea which would partially obstruct expiration without, in any way, affecting inspiration. Fig. 1 shows the valve in position in the trachea. This experiment led the authors to believe that a possible relationship exists between eosinophilia and mechanical expiratory dyspnea.

Previously, Freedman and Jackson¹ produced temporary expiratory obstruction in dogs for the purpose of studying the carbon dioxide values of the blood and of alveolar air. Their obstruction was brought about by employing a one-way valve attached to a tracheal T-tube. The results were obtained during experiments conducted under anesthesia.

Later, Pescatori² produced respiratory insufficiency by blocking the trachea with oil or tap water. Under these conditions he reported an eosinophilia which ran from 5 to 25 per cent. Unfortunately, it was impossible by this local edema method to maintain a constant tracheal pressure. Neither did this method permit regulation of the expiratory phase of respiration without affecting normal inspiration, because tracheal edema per se will alter both phases of respiration. Pescatori believes that the chronic stimulation of the tissues resulting from pathologic conditions, such as pneumothorax, pleurisy, etc., is of an acidotic nature and that this is the cause of the accompanying eosinophilia. To support this theory he poisoned rabbits rapidly with carbon dioxide (asphyxia) and obtained a high grade eosinophilia.

In our experiments blood studies were made before inserting the valve in the trachea of dogs to ascertain normal eosinophile values, and daily thereafter, during intubation. Further studies were carried during the acute asthma attacks and lastly at intervals following the spasms. The results of these studies are tabulated in Table I.

Our observation periods for dogs varied from twenty-four hours to seven days. During these periods aside from the expiratory dyspnea (asthma attack) which was purposely elicited (by exercise or the inhalation of tobacco smoke) for blood sampling, the general health of the animals was excellent.

In this table data are presented showing that, following the retardation of the expiratory phase of respiration, the eosinophile count increased on an

average of 4 per cent, which was upon occasion increased by exercise or inhalation of smoke as high as 18 per cent. The type of respiration thus brought about produced in the animals every clinical point required for the diagnosis of asthma; and in addition, continued expiratory difficulty resulted in permanent emphysema.

In each case the total white cell count increased shortly after intubation, in two cases going as high as 15,000. This leucocytosis corresponds with that found in human beings during exercise. The eosinophile count increased to an average of 4 per cent on the first day, and to a maximum of 18 per cent in Dog 7 on the fourth day.

Each of these dogs exhibited eosinophilia after intubation, and developed a perfect pulmonary emphysema. Shortly after intubation fine whistling râles could be heard all over the chest, which were accentuated by exercise and

Fig. 1.—Dog 6, weight 12 kilos. Anteroposterior view of intratracheal ball valve in position.*

inhalation of irritants. This would indicate the added factor of bronchospasm, the total picture being identical with bronchial asthma. Of interest is the fall in eosinophile percentage in Experiment 6 following spontaneous extubation while physical signs of emphysema persisted. Reintubed this animal again showed an eosinophilia but of a higher grade. After exercise or inhalation of tobacco smoke, the eosinophilic count doubled; whereas, after extubation it remained at a normal level even though there were definite objective signs of emphysema.

The textbook³ statement that eosinophilia accompanies emphysema did not hold true in Dog 6 following valve removal, even though all the desired physical signs of emphysema such as extension of the areas of pulmonary resonance and hyperresonant percussion note over both lungs were present. In this experiment the typical wheezing prolongation of the respiratory murmur dis-

appeared with removal of the mechanical factor; and with the return of normal expiration the eosinophile count fell from 9 to 1 per cent. The degree of emphysema developed in this experiment is shown in Figs. 2 and 3, the first taken before intubation and the second six days later following five days of expiratory difficulty. The autopsy report* of this experiment which follows is also negative for eosinophiles, but confirms the clinical picture of emphysema.

PATHOLOGIC FINDINGS

"Specimen consists of two lungs. They are pale, soft, and crepitant. The margins are ballooned out, almost white in color and the alveoli are quite visible as minute cysts. Scattered throughout the upper lobe is a rather irregular mottling of the same process. The middle lobe is normal except along the margins and the same is true of the lower lobe.

"The second lung composed of four lobes shows a similar process, the margins are pale, noncollapsed. The upper lobes show a spotty pallor which becomes less and less noticeable in the lower lobe where only the marginal portion shows this distended condition.

"Diagnosis.—Emphysema: Bronchi are distended, very pale, contain no visible mucus or blood.

"Smears from bronchi show little mucus, desquamated epithelial cells, few mononuclear cells containing pigment. Smears for bacteria were negative, Wright's smear failed to show eosinophiles.

"The striking lesion in the parenchyma is the irregular dilatation of the alveoli, which is best seen toward the peripheral portion of lung tissue. Here, the alveolar walls are extremely thin and æmemic, and the alveolar spaces are three to four times as large as normal; bordering an area of alveolar dilatation are small patches of collapsed lung tissue.

"The bronchioles are distended.

"The walls of the vessels are normal except in a few branches of the pulmonary artery, which contain fibrin clumps that are undergoing organization.

"The glands along the bronchi and bronchioles as well as the mucosa are normal. The cilia stand out clearly, bathed by a very delicate layer of clear mucus.

"Occasional pigmented mononuclear cells are seen in the alveolar spaces and in the bronchial secretion.

"Differential count of white blood cells in large vessels shows normal count with no eosinophilia.

"Examination of stroma surrounding bronchi and bronchioles shows no increase in cellular exudate and no infiltration of eosinophiles.

"Small fresh petechial hemorrhages are scattered throughout the lung parenchyma.

"Microscopic Diagnosis.—Parenchymatous emphysema, focal atelectasis; organizing thrombi in branches of pulmonary artery; petechial hemorrhages into alveolar spaces."

It is difficult to parallel this type of uncomplicated emphysema in human beings because such a condition does not call for hospitalization. Table II shows blood counts in selected cases. (All blood counts reported are averages of five or more taken at various times during the patient's illness.)

Fig. 2.—Dog 6. Anteroposterior view of chest before intubation, showing normal lung expansion.

In these cases of human emphysema all are complicated by pulmonary or bronchial pathology, with the exception of Case 2. This case was atrophic and of senile type, having no history of cough, and of interest since eosinophiles were practically absent in the blood smears.

The remaining cases all show a substantial eosinophilia. The high eosinophile count in the bronchial asthma case is explainable on the basis of bronchial spasm and expiratory dyspnea. In the remaining cases the emphysemas were complicated by chronic bronchitis coupled with a history of severe cough of long duration. During each cough there is a transitory overdistention of the lung, and this momentary obstruction to expiration is sufficient to cause both emphysema and eosinophilia and is similar to the eosinophilia and emphysema which we have produced experimentally.

In order to time the appearance of eosinophilia we studied the values produced by expiratory resistance upon medical students. Oral expiration was prolonged by employing a partially blocked flutter valve, the resistance offered varying from 20 to 30 mm. mercury pressure. Inspiration was through the nose. The results are tabulated in Table III.

The average time was two and one-fourth minutes, and the average degree of eosinophilia prior to and during dyspnea was 0.43 per cent and 7.19 per cent, respectively. In one-third of these cases the average eosinophilia was over 11 per cent. Hence, the eosinophilia occurring during dyspnea was approximately sixteen times greater than that prior to dyspnea.

FIG. 3.—Dog 6, Anteroposterior view of chest six days after intubation showing extent of emphysema development.

We also believed it worth while to determine whether or not asthma, when temporarily relieved by adrenalin medication, was accompanied by changes in the eosinophilia count.

Table IV gives the results obtained in human cases, showing no eosinophile change under adrenalin. For completeness we have included negative results detailed in Table I, both as to spasm relief and eosinophilia change in dogs. One would expect lack of relief where mechanical conditions which from their nature and location would be the sole, specific and exciting cause of expiratory delay and alveolar distention.

Camp⁴ has reported that the eosinophiles are markedly increased by adrenalin dosage. Our investigation of this phase is negative both in human beings and dogs, and we are unable to account for his positive findings.

That the other human cases show an eosinophilia is explainable on the basis of accompanying respiratory difficulty.

The possibility of adrenalin raising the eosinophilic index had proved negative in our tests as shown in Table I, and also in Table IV.

In this short series of human cases of allergic disease accompanied by eosinophilia there was no fall in eosinophilic count many hours after adrenalin, even though the dosage was adequate to give symptomatic relief. This continued eosinophilia rules out the possibility of delayed adrenalin action.

DISCUSSION

Prior to the experiments of Pescatori,² Freedman and Jackson¹ showed that the CO_2 content of the blood and alveolar air is raised when expiration is partly obstructed, but these authors did not investigate the blood picture. One would expect such an increase in CO_2 tension when the retarded expiration was reinforced by an anesthesia.

The theory advanced by Pescatori, that the increase in eosinophiles is brought about by the above conditions, is based upon poisoning rabbits rapidly with CO_2 (asphyxia). By this method he obtained a high degree of eosinophilia, i.e., 35 per cent.

In the production of asphyxia there is a condition which closely parallels our mechanical retardation of expiration, because certainly the second stage of asphyxia is characterized by expiratory convulsions.

The cause of this sudden and apparently selective action accompanying bronchospasm, we believe, is due to the overdilatation of the alveoli which, in turn, initiate reflex peripheral stimuli which brings about a release of eosinophiles from blood-forming organs. Garrey and Butler⁵ believe a similar mechanism is accountable for the temporary leucocytosis resulting from sudden distention of the stomach.

The degree of individual response varied, as shown in Table III, but the striking phenomenon is that in all cases sudden definite eosinophilia developed. The rapidity of this eosinophilic release is indicative of reflex action upon blood-forming organs and blood reservoirs. The source of these eosinophiles is probably the reservoirs because of the rapidity of response and the maturity of the cells (multi lobulated nuclei).

The leucocytic increase in our experiments is definite. If there were nothing specific in the release of eosinophiles their increase should be proportional to the leucocytosis. But the percentage increase in leucocytosis is relatively small compared to the percentage increase of eosinophiles, which again suggests that a release of eosinophiles is probably due to some specific entity.

Additional evidence that CO_2 (chemical stimulation) is not the factor is to be found in the uncomplicated case of emphysema in Table IV: also in Animal 6, Table I, following extubation. In both of these cases the eosinophilic index is not raised although it has been shown by Dautraban⁶ and others that in emphysema there is an increase in CO_2 tension.

Recently Martin,⁷ in his study of the effects of exercise upon leucocytosis, investigated also the reactions of the white cells under adrenalin. His results show that both exercise and adrenalin increase the total white blood cell count, principally the lymphocytes and the polymorphonuclear cells. Investigation of the effects of exercise upon the eosinophilic index was negative, although our total counts confirmed Martin's conclusions. Analysis of Martin's tables show that under adrenalin medication the greatest individual increase of eosinophiles was 1 per cent. In this case the initial count was 2 per cent before adrenalin and 3 per cent after. Other cases in his series show decreases under adrenalin, while the remainder show increases varying from 0.05 to 0.75 of 1 per cent. Certainly the minor increases reported by Martin could not be considered clinical increases, nor do we feel that his reported decreases up to 1½ per cent under adrenalin are of significance. One would expect just such slight variations in individuals.

As a result of our experiments a physiologic explanation is to presume that there is a temporary eosinophilia during the prolonged and forceful expiratory act, as for example, in whooping cough, blowing of wind instruments and glass blowing. That the data relative to eosinophilia in these conditions are lacking is explained by the fact that counts have not been carried out during the period of expiratory exertion.

It is an established custom for clinicians to associate eosinophilia as a definite blood finding of allergic phenomenon. We contend that the "allergic doctrine" confuses cause and effect, because in so-called allergic conditions there is frequently bronchospasm coupled with alveolar overdistention which produces eosinophilia. Eosinophilia, per se, does not suggest certain protein avoidance nor does it demand sensitizing tests.

CONCLUSIONS

1. Eosinophilia is produced by expiratory delay when accompanied by overdistention of the alveoli.
2. Evidence is offered which suggests that this response is specific and of a reflex nature.
3. Adrenalin does not affect the eosinophilic index.
4. The evidence available does not warrant the consideration of acidosis as a causative factor in eosinophilia.
5. Physiologic leucocytosis is not accompanied by eosinophilic increase.
6. Eosinophilia, per se, is not pathognomonic of allergic diseases.

FURTHER STUDIES ON THE CULTIVATION OF *ENDAMEBA HISTOLYTICA* AND A COMPLEMENT FIXATION TEST FOR AMEBIASIS*

H. TSUCHIYA, Sc.D., St. Louis, Mo.

I. CULTIVATION OF *ENDAMEBA HISTOLYTICA*

THE general belief that *Endameba histolytica* does not ordinarily ingest intestinal bacteria was contradicted by Boeck and Drbohlav¹ on the basis of their cultural experiments. They showed that the amebas were able to ingest bacteria, and consequently, they believed that the organisms might thrive without access to tissue elements. The work of Dobell and Laidlaw² as well as Cleveland and Saunders³ seemed to strengthen this contention. Dobell claimed that certain particular types of intestinal bacteria were especially favorable sources of food supply for the amebas. By the addition of such organisms, he succeeded in maintaining a cultural cycle of the amebas in vitro. Cleveland and Saunders cultivated the amebas from apparently bacteria-free amebic abscesses in the medium of Cleveland and Collier⁴ and found that the amebas were able to multiply very rapidly when *Escherichia communior*, *Vibrio comma*, and *Neisseria catarrhalis* were present.

Though Kofoed and Wagener⁵ believed that either coagulated egg or blood was required as a source of food for the amebas, Yorke and Adams⁶ considered moisture and a suitable temperature (37° C.) to be the only essential factors in inducing excystation of the organism in vitro. They reported that excystation occurred when cysts were placed in either Locke-serum, broth, or physiologic saline and incubated at 37° C. for a few hours, but a total disintegration of the organisms occurred in these mediums after several hours' incubation. In view of these findings it occurred to the author that the addition of suitable substances to one of these media might result in the survival of amebas beyond the stage of excystation.

The purpose of this study is to describe a method of cultivation of amebas, worked out with these experiments as a background. The details of the method have been somewhat modified since the original report on the subject.⁷

The method developed consists of the inoculation of washed cysts into a medium tentatively called S. C. medium composed of nutrient broth and a mixture of starch and charcoal with and without Dorsett's egg medium.⁸

Constituents of the Medium.—1. *Nutrient Broth* consisted of peptone 10 gm., meat extract 3 gm., and NaCl 5 gm. in one liter of distilled water adjusted to P_H 7.0 and autoclaved at 15 pounds' pressure for thirty minutes. The P_H of the medium within the range of 6.8 and 7.4 also answers the purpose, though the optimum is found to be 7.0.

*From the Department of Bacteriology, Immunology and Public Health, Washington University School of Medicine.

Received for publication, April 3, 1933.

I wish to express my gratitude to Doctor J. Bronfenbrenner for his valuable advice and criticism during the course of this study.

2. *The S. C. Mixture*.—This is a thoroughly triturated mixture of rice starch and animal charcoal in the proportion of 2:1 by volume. A small amount of the mixture is loosely placed in a small vial and sterilized by dry heat at 180° C. for forty-five minutes.

Rice starch provides the amebas with a definite source of assimilable carbohydrate and inhibits the growth of *Blastocystis* frequently met with in feces. The addition of rice starch by Dobell and Laidlaw to the original medium of Boeck and Drbolav has been generally considered as a decided improvement, as extremely small grains of rice starch are readily ingested by the amebas.

Animal charcoal is used to adsorb ammonia and hydrogen sulphide thus reducing their deleterious effects upon the amebas, and inducing a partial anaerobiasis in the medium by the adsorption of oxygen. The relative value of charcoals of various origins have been studied. Merek's purified animal charcoal and Norit were found to be superior to others for this work. The calcium phosphate contained in these charcoals acts as a buffer, and also helps to stimulate the metabolic activities of the amebas. It was found that the addition of excess calcium phosphate to the medium did not materially increase the growth of the amebas, but on the contrary stimulated a marked proliferation of the accompanying bacteria, so that the amebas were crowded out.

Preparation of Washed Cysts.—This is carried out best according to the method of Hegner.⁹ Formed stool is thoroughly mixed by means of a sterile glass rod or spatula in order to obtain a uniform distribution of cysts. Liquid stool should first be sedimented, and the supernatant fluid carefully decanted. A portion of stool or sediment thus obtained is emulsified with a large quantity of water. This is filtered through four layers of gauze into a tall cylinder and allowed to stand for a few hours during which time cysts settle to the bottom. The process is repeated at least three times, until the sediment is found to be composed of the cysts and a small amount of debris. The sediment thus prepared, as a rule, contains fewer bacteria than are present in original stool. There is an especially noticeable reduction of the starch-splitting types of organisms, as is indicated by the presence of numerous unchanged starch granules in the medium after incubation.

When sufficient time is not available for the preparation of washed cysts, a portion of the sediment obtained from the preliminary filtration is transferred to a 15 c.c. centrifuge tube. By an addition of sufficient distilled water, this is washed by means of centrifugalization at 1,500 r. per minute for three minutes. This process should be repeated at least three or four times. Cysts, thus collected, were found to grow in the culture medium almost as well as those obtained by the slow sedimentation.

The author¹⁰ recently found that washed cysts remained viable as long as nine days when left at room temperature (22° C.) and thirty-five days in a refrigerator. Furthermore, irrespective of the stages of development of these cysts, they were found to grow to maturity in vitro under favorable environmental conditions. Hegner, Johnson and Stabler¹¹ observed that immature cysts were able to excyst in the small intestines of monkeys within three hours after being introduced into the stomach. A successful cultivation in vitro,

therefore, appears to depend on the number and viability of cysts inoculated, but not upon the stage of development of these cysts as previously considered.

Primary Cultures.—At the outset of this investigation, it was thought that an introduction of a small bit of an infected stool into the medium was sufficient to induce a good growth of the amebas. Subsequent studies, however, indicated that washed cysts were superior for the cultivation irrespective of the number of cysts found in the original stool. Apparently, the growth of the amebas was prevented by multitudes of bacteria present in the original stool.

A small amount of washed cysts (0.1 c.c. or less dependent upon the number of cysts present) is introduced into 8 c.c. of the broth previously warmed to body temperature, and two 4 mm. loopsful of the S. C. mixture are added. The tube is now incubated at 37° C. After an incubation period of from twenty-four to forty-eight hours, the sediment is at first gently seraped off from the bottom of the tube by means of a pipette with a wide terminal opening, and then about 0.1 c.c. or less is withdrawn carrying with it minute particles of charcoal. The amebas are usually found adhering to the particles of charcoal at the bottom of the tube. The organisms, if few are present, therefore, may readily escape detection in a material without charcoal. The contents of a pipette are spread on a warm clean slide, covered with a cover glass, and examined by means of a 10 x eye piece and 16 mm. dry objective, preferably either on a warm stage or in a warm chamber. Some of the amebas, at first seemingly quiescent, soon begin to project their pseudopodia explosively. Within a few minutes some of them are found crossing the microscopic field with rapidity and in a definite direction in an apparent search for food. As a rule, within the cytoplasm of the motile amebas there are observed fewer starch granules than within the quiescent ones. The amebas, if kept warm and moist, exhibit markedly progressive locomotion, as observation continues. The addition of a small drop of 0.1 per cent neutral red helps to differentiate the ectoplasm from the endoplasm without affecting the motility of the amebas, and facilitates the examination greatly, as it gives the endoplasm a pinkish refractive tinge as contrasted with other objects in the microscopic field. Care should be taken to guard against air currents and desiccation of the specimen, as this may interfere with the motility of the amebas, thus inducing them to round up and die.

By the use of this medium, the amebas may often be seen at various stages of development; excystation, metacystic development and encystation as well as division frequently occur simultaneously. The extent of growth of the amebas in this medium is very striking. Thus, by the introduction of 80 cysts, the number of the trophozoites was calculated to be 21,200 after forty-eight hours' incubation in one instance, while, in other instances, 40 cysts gave rise to 13,900 and 72 cysts to 12,200 trophozoites.

While the medium seems to be very favorable one for *E. histolytica*, it does not seem to support the growth of other protozoa. Repeated attempts to grow *E. coli*, *E. nana*, and *I. williamsi* in this medium were without results. The same also holds true to a certain extent with the flagellates such as *Trichomonas hominis* and *Chilomastix mesnili*; these organisms grow quite readily in the absence of the S. C. mixture from this medium. Though no plausible explanation can be given at this time, it is suggested that P_H of the medium and the

nature of the bacterial contents, as well as the oxygen tension may not be suitable for these organisms.

Subcultures.—Subcultures may be made by inoculating a small amount of the sediment from the primary culture to a fresh tube of the original culture medium previously warmed to body temperature. Transfers should be made at least every forty-eight hours in order to induce a good growth.

It has also been found that when about 5 c.c. of the S. C. medium is superimposed on a slant of Dorsett's medium, an efficient medium for subculturing and primary cultures* is obtained. With careful manipulation, this medium serves to maintain luxurious growth of the amebas through many generations when transfers are made at twenty-four-hour intervals. The amount of the inoculum should not be greater than 0.05 c.c., as the excess often leads to the overgrowth of the accompanying bacteria which interferes with the optimum cultural environment for the amebas.

Maintenance of Cultures.—When washed cysts are first exposed to the action of a mixture of equal volume of gentian violet and acriflavin (1:100 dilution each) at 37° C. for one hour, and then inoculated into the S. C. medium on Dorsett's medium slants, the amebas usually maintain growth for as long as eight days without further transfer. In these circumstances the lag period before detectable evidence of growth is prolonged, but the development thereafter is remarkably luxuriant. The long lag period may be accounted for by the amebastatic activities of these dyes, such as had been observed by Churchman¹² in the study of bacteriostasis. The detailed study of this problem will be reported at a later date.

Diagnostic Value of the Culture Method.—The superiority of the cultural method over the direct microscopic examination and concentration methods for detection of amebas in stools was clearly shown by the fact that, of 346 stools examined at random for intestinal parasites, 5, or 1.44 per cent were positive for *E. histolytica* by the direct microscopic examination of the stools, 7, or 2.02 per cent, by the concentration method of Rivas,¹³ and 9, or 2.60 per cent, by the use of this medium. In each instance, the final verification of the organism was made by permanent preparations which were stained by the method recently described by the author.¹⁴ The cultural method, if properly employed, therefore, is of considerable value in the routine diagnosis for the presence of *E. histolytica*. Furthermore, the fact that other endamebas failed to grow in this medium adds to its value for diagnostic use.

II. COMPLEMENT FIXATION TEST FOR DIAGNOSIS OF AMEBIASIS

Craig¹⁵ has reported positive complement fixation tests in 92 per cent of a group of 84 cases of amebic infection, all of which showed the amebas in the stools. Recently, Keifer,¹⁶ aided by Craig, reported strongly positive complement fixation reactions with the same antigen (prepared from amebic culture in Boeck and Drbolav medium) in 15 out of 19 cases of chronic ulcerative colitis, but neither feces nor materials obtained by means of the proctoscope revealed the presence of the amebas in these cases. The question naturally arises as to the

*See additional note in abstract, Further Studies on the Cultivation of *Endameba histolytica*, J. Parasit. 20: 143, 1933.

significance of the positive reactions in these instances. They might conceivably be due to the presence of amebic lesions outside of the intestine. It is possible, though unlikely, that the positive reactions were caused by existence of complement fixing antibodies in the patient's serum for the bacteria in the antigen preparation used. Keifer suggested the possibility that the pyogenic infection of the colon in these cases might be superimposed upon a preexisting amebic ulceration and cited in support of this the disappearance of symptom in some of his cases following antiamebic therapy. There is, however, no direct evidence that infection with the amebas was the causative factor in any instance. The beneficial effect of emetine therapy by no means constituted proof of amebic infection.

The purpose of the present study is to further investigate the value of complement fixation tests in diagnosis using as an antigen the culture in the medium devised by the author.

Reagents.—One of the obstacles in perfecting the complement fixation procedure is the difficulty in separating the amebas completely from the accompanying bacteria in vitro so as to prepare a specific antigen. The selection of material suitable for preparation of the antigen requires utmost consideration, particularly with reference to (1) the number of bacteria in the original stool in proportion to that of the amebas, and (2) the choice of a culture method which will further reduce the number of bacteria and will stimulate the growth of the amebas.

Antigen: For the preparation of the antigen, Craig¹⁷ utilized the Boeck-Drbolav medium¹ containing 2 or 3 amebas per microscopic field, while Menendez¹⁸ used the material containing 8 or 10 per high power microscopic field. Hage¹⁹ in his attempt to confirm Izar's²⁰ work with the complement fixation reaction attributed his failure to a lack of sufficient number of amebas to be extracted for the aqueous antigen. Because of the small number of amebas present Craig used in his work an undiluted antigen. The number of the amebas in the antigen in my study was considerably greater than in those of Craig and Menendez; the average number per high power microscopic field being 54. Repeated titrations of the antigen indicated that dilutions lower than 1:100 showed anticomplementary property. One-fourth of the anticomplementary unit of this 1:100 dilution was employed in the test.

Owing to the presence of the amebas only on or below the level of charcoal in the S. C. medium, no preliminary centrifugalization was deemed necessary to obtain the material to be extracted. The supernatant fluid above the charcoal was carefully pipetted off. The sediments of at least 24 cultures including the charcoal and starch were collected and placed in a conical centrifuge tube with an addition of warm normal saline solution. This was repeatedly centrifuged at slow speed, until the sediment contained a comparatively small number of the accompanying bacteria. Usually, seven or eight centrifugalizations were necessary to accomplish this end. By following the method of Craig, to one volume of the sediment was added ten volumes of absolute alcohol. The mixture in a tube, hermetically sealed, was left in an incubator at 37° C. for fifteen days, having been shaken vigorously at least three times a day during this

period. At the end of the period, the mixture was filtered through a fine filter paper, and the filtrate kept in a refrigerator until used.

In addition to the above, a second antigen was prepared by evaporating 10 c.c. of the above extract in an incubator at 37° C. until 1 c.c. mark was reached, and the evaporated portions replaced with normal saline solution.

As controls, extracts were also prepared in a similar way from the accompanying bacteria in the culture medium.

These antigenic preparations were titrated about every three weeks in order to check their potency.

Other Reagents: The hemolytic system used consisted of a 10 per cent sheep cell suspension, guinea pig complement (40 per cent) and rabbit antsheep amboceptor.

Test Proper: In this study, the ice box method of complement fixation was employed. To 0.1 c.c. of unknown serum, previously inactivated at 56° C. for half an hour was added one-fourth of anticomplementary unit of the antigen, and 2 units of complement. The tubes were left in a refrigerator for eighteen hours. One-tenth cubic centimeter of 10 per cent red cell suspension and 2 units of amboceptor were then added to each tube, and the incubation carried out in the water-bath at 37° C. for half an hour. Controls were run with known positive sera from cases of proved amebic infection and with normal sera, and the usual reagent controls. In the earlier part of the work the patient's sera were tested in various dilutions. The final readings were made after allowing red cells to settle sufficiently to the bottom of the tubes. For this purpose, the tubes are usually left in a refrigerator for two hours after the removal from the warm water-bath.

RESULTS AND DISCUSSION

TABLE I

CORRELATION BETWEEN RESULTS OF COMPLEMENT FIXATION TESTS AND ORDINARY DIAGNOSTIC METHODS*

CLINICAL DATA	TOTAL CASES	COMPLEMENT FIXATION POSITIVE. ORDINARY DIAGNOSTIC METHOD POSITIVE	COMPLEMENT FIXATION NEGATIVE. ORDINARY DIAGNOSTIC METHOD NEGATIVE	COMPLEMENT FIXATION POSITIVE. ORDINARY DIAGNOSTIC METHOD NEGATIVE	COMPLEMENT FIXATION NEGATIVE. ORDINARY DIAGNOSTIC METHOD POSITIVE
No evidence of amebiasis	130	—	130	—	—
Amebic dysentery	6	5	—	—	1
Carrier of <i>E. histolytica</i>	8	8	—	—	—
Suspected amebiasis	4	—	—	4	—
Ulcerative colitis	5	—	5	—	—
Totals	153	13	135	4	1

*Includes microscopic concentration and cultural examinations of stool and of material obtained by proctoscope (in some cases).

The comparison of examinations of stools and materials obtained by proctoscope with the findings in complement fixation tests with *E. histolytica* are shown in Table I. Both the feces and sera were found to be negative in 135 instances. In 13 cases of diagnosed or suspected infection the results were

positive both in feces and serum, while 4 gave a positive serum with a negative stool and one a negative serum with positive stool finding.

Judging from these observations, a negative reaction would appear to be quite significant if the tests were employed in the routine diagnosis, and would be of value in eliminating the possibility of amebiasis in a given individual. However, if repeated examinations were carried out, the number of positive stool findings might have been higher than that reported in this study. The author⁹ recently observed the presence of definite encystment cycle in a carrier of *E. histolytica*, as he had recognized in those of *Giardia lamblia*.²¹ Owing to considerable fluctuations in the number of cysts discharged from day to day, it was suggested that the examination of stools be made on alternate days for a longer period, rather than six consecutive days as advocated by Dobell.²² The necessity of frequent examination cannot be overemphasized, as is illustrated in the following instance:

In a patient giving the history of protracted diarrhea accompanied by the profuse discharge of blood and mucus, the repeated complement fixation tests were consistently positive. The repeated examinations of stools and of materials obtained by means of proctoscope failed to show any amebas until finally on the fourth examination (a warm specimen), motile amebas were detected. Among eight individuals free from clinical symptoms but known to be carriers of *E. histolytica* and giving positive complement fixation tests, the cysts were detected in the stools only after repeated examinations in some instances.

Of the 6 patients with amebic dysentery 5 exhibited strongly positive complement fixation reactions and the initial stool examinations revealed presence of *E. histolytica*. These patients showed ulcerative areas about the rectum and sigmoid which teemed with actively motile amebae ingesting many red blood cells. The remaining case of amebiasis (with positive stool) never showed any capacity to fix complement in repeated trials.

With respect to the 4 cases with negative stools but positive complement fixation reaction, the following possibilities may be considered: (1) the amebas might have become localized in the tissues only, while the intestinal lumen was devoid of their presence (such may occur in case of metastasis to other parts of body), (2) there may have been an insufficient number of stool examinations to reveal the amebas, or (3) the amebic lesions may have been too high in the intestine to permit detection by the proctoscope. Such lesions are frequent, judging from the works of Hutchinson²³ and Callender.²⁴ Clark²⁵ reported in his study of 186 postmortem examinations in the Panama Canal Zone that the ulcers were most frequently found in the cecum, the portion where the greatest stasis existed. In such, no ulcerations were detectable by the proctoscopic examinations. Low²⁶ claimed that the practical value of sigmoidoscopic diagnosis is very much limited, as autopsy often revealed dysenteric lesions in the cecum and other portions of the large intestine with no rectal involvement.

It is interesting to note that in the five cases diagnosed clinically as chronic ulcerative colitis both complement fixation tests and repeated microscopic examinations revealed no evidence of amebic infection.

In the majority of the cases showing positive complement fixation, there were concomitant intestinal protozoan infections with organisms such as *Giardia lamblia*, *Chilomastix mesnili*, *Endameba coli*, *Endolimax nana* and *Iodameba williamsi*. These, however, did not influence the serologic findings. Among those individuals giving negative tests, there were several who harbored intestinal protozoa other than *E. histolytica*.

The results of the complement fixation reactions carried out using bacterial extracts as antigen consistently gave negative reactions irrespective of the outcome of the reaction with the amebic antigen. This confirms the findings of Craig as well as Sherwood and Heathman.²⁷ However, the bacterial extracts prepared in this study cannot be considered quite adequate, since the bacterial flora is variable according to individuals, and from time to time in the same individuals. It is still possible that some of the positive fixations obtained in clinically negative cases are due to this factor alone.

Prior to carrying out the complement fixation tests for *E. histolytica*, the majority of the sera were submitted to Wassermann or Kahn test or both in the Clinical Laboratories of the Department of Internal Medicine. It was found that existence of syphilis did not affect the specificity of the test. This confirms the previous findings of Craig and also of Spector.²⁸

COMMENT

Hegner²⁹ has recently suggested that there are at least several types among the amebas according to their sites of localizations, each differing in their morphologic and physiologic characteristics, and that the universal conception that the tissue amebas give rise to the lumen types appears to be erroneous. He based his opinion upon histologic studies of the infected intestine which revealed no apparent tissue invasion. Judging from these observations, the formation of antibodies in response to the parasitic invasion may be variable according to the type of the amebas in question. It may be that antibody response is lacking in the case of the lumen and stool types, and this may explain the single instance reported above in which there was a negative complement fixation reaction with a positive stool.

Craig³⁰ has emphasized the fact that carriers, although showing no apparent symptoms, nevertheless usually presented definite pathologic lesions in the intestines at autopsy. It is probable that this explains the positive results in the complement fixation reactions in the 8 cases reported in this paper.

SUMMARY

1. A new culture medium (S. C. medium) for *E. histolytica* is described. By virtue of its simplicity and apparent efficiency, it is suggested that cultures in this medium may be valuable as a part of the routine diagnosis of infections with *E. histolytica*. The culture medium when superimposed upon Dorsett's egg slant serves very well for primary and subcultures. The fact that in these mediums other endamebas fail to grow seems to be of decided advantage in diagnosis.

2. When complement fixation tests were carried out with an antigen prepared from amebas cultured in the above medium, the following results were

obtained: Of 153 individuals examined, 135 known to be free of amebic infection, all were found to give a negative serologic test. Of the remaining 18 cases, 8 were known carriers of *E. histolytica* and gave positive serologic reactions. Six were diagnosed as clinical amebic dysentery and exhibited positive serologic reaction except in one case in which repeated trials failed to show any capacity to fix complement. There were 4 cases of ulcerative colitis which showed positive serologic tests, but no amebas were detected in the examinations of stools.

Thus, a negative serologic test appears to be quite significant, and valuable for eliminating the possibility of amebiasis in a given individual. A positive serologic test also seems to be quite specific in demonstrating the presence of *Endameba histolytica*.

A STUDY OF THE SALIVARY AMYLASE IN PATIENTS WITH PERNICIOUS ANEMIA*

CHARLES P. EMERSON, JR., B.S., AND O. M. HELMER, PH.D.,
INDIANAPOLIS, IND.

PATIENTS with pernicious anemia are known to be subject to glossitis and often have involvement of the buccal mucous membrane. Since the ducts of the salivary glands open into the oral cavity, it was felt that it would be of interest to determine the amylolytic activity of the saliva, in order to ascertain whether the salivary glands were involved similarly. Carles and Delmas-Marsalet,¹ in 1924, reported that the amylolytic power of the saliva was lowered in cachectic states, such as tuberculosis, and increased in patients with peptic ulcer, indicating a possible parallelism with the gastric juice acidity.

The gastric juice findings of the patients presented in this paper have been previously reported by Helmer, Fouts, and Zerfas.² All of the patients had an achylia gastrica after histamine stimulation and were clinically and hematologically typical of pernicious anemia. Healthy adults with normal gastric juice acidity after histamine stimulation were used for controls.

METHOD

The method employed consisted essentially in the digestion of a starch solution with saliva diluted to a suitable concentration and the determination of the glucose formed by the resulting hydrolysis. Results, satisfactory from the comparative standpoint, were obtained, using a substrate consisting of 5 c.c. of a 1 per cent starch solution, unbuffered, and containing no added activating substances. Samples of saliva were collected a minimum of two hours after the ingestion of food or sweets, the flow of salivary secretion having been stimulated by the chewing of paraffin. The saliva was then filtered and diluted to a concentration such that 1 c.c. of the solution incubated with the substrate for one-half hour at 40° C. would hydrolyze between 0.4 mg. and 1.5 mg. of

*From the Lilly Laboratory for Clinical Research, The Indianapolis City Hospital and the Department of Medicine, Indiana University School of Medicine.
Received for publication, March 15, 1933.

glucose. The glucose content of the resultant mixture was determined by the revised method of Folin.²

The limits of true proportionality (0.4 mg. and 1.5 mg.) were determined experimentally by the digestion of 1 per cent starch with 1 c.c. samples of the same saliva diluted in the following proportions with water: 0.4 per cent, 0.6 per cent, 0.8 per cent, 1.2 per cent, 1.6 per cent, and 2.0 per cent. The amounts of glucose that were formed on hydrolysis are shown in Table I.

TABLE I

THE AMOUNT OF GLUCOSE PRODUCED BY DIFFERENT DILUTIONS OF THE SAME SALIVA

SAMPLE	PER CENT SALIVA	MG. GLUCOSE
1	0.4	0.41
2	0.6	0.50
3	0.8	0.68
4	1.2	1.01
5	1.6	1.41
6	2.0	2.06

Apparently the small amount of reducing substances ordinarily present in soluble starch had little influence on the resultant values, at least so far as a comparative effect was concerned, within this range, and it was unnecessary to consider a blank determination inasmuch as the same starch was used throughout.

Since the salivary amylase is so active, cotton plugs were placed in the pipettes to prevent contamination. The water-bath was carefully regulated, and the incubation was carefully timed from the addition of the enzyme to its destruction by the Folin-Wu copper sulphate reagent. The starch solution deteriorates rapidly at room temperature, so it was either made up daily or preserved with toluene, which did not interfere in the determination.

TABLE II

THE AMYLOLYTIC ACTIVITY OF THE SALIVA OF PATIENTS WITH PERNICIOUS ANEMIA AND OF NORMAL CONTROLS

	CASE	DILUTION OF SALIVA	MG. GLUCOSE	UNITS
Pernicious anemia	1	1.0%	1.61	161
	2	0.5%	0.65	120
	3	0.1%	0.75	750
	4	0.5%	0.68	136
	5	0.5%	1.04	208
	6	0.2%	1.24	620
	7	0.4%	0.65	162
	8	1.0%	1.68	168
	9	1.0%	1.17	117
	10	0.1%	0.67	670
	11	0.3%	1.22	406
	12	0.5%	1.31	262
	13	0.5%	1.25	250
	14	0.5%	1.42	284
Normal	1	0.5%	0.80	160
	2	0.5%	0.73	146
	3	0.5%	0.92	184
	4	0.3%	1.57	525
	5	0.5%	0.58	116

For means of comparison, a unit of activity was adopted, namely, the quantity of enzyme necessary to hydrolyze 1 mg. of glucose under the conditions described.

RESULTS

The results of the analysis are shown in Table II. Although the values varied enormously among different individuals, determinations on the same subject over periods of weeks demonstrated but slight variations. These results would indicate that the amylolytic activity of the saliva was not decreased in patients with pernicious anemia. Since all of these patients had an achylia gastrica, the degree of acidity of the gastric juice bore no relation to the activity of the salivary amylase. Furthermore, since patients with pernicious anemia have no free hydrochloric acid in their gastric juice, a considerable amount of starch digestion could take place in the stomach.

SUMMARY

1. A technic is described suitable for the quantitative determination of salivary amylase.

2. No demonstrable deficiency could be found in salivary amylase in patients with pernicious anemia.

The authors wish to express their thanks to Doctor L. G. Zerfas for his kind interest in the work.

SICKLE CELL ANEMIA*

A CASE REPORT

R. H. McCLELLAN, M.D., AND R. M. ENTWISLE, M.D., PITTSBURGH, PA.

THE importance of careful routine laboratory procedures is often minimized. In the case to be reported, the diagnosis, uncertain at first, and the explanation of several obscure physical findings, were at once made clear by the study of the stained blood smears taken by routine. Fradkin and Schwartz¹ say: "It is only by the accidental discovery of the sickle cells in the routine examination that the diagnosis is made." The word "accidental" should be unnecessary.

A brief review of the usual symptoms and findings in sickle cell anemia includes the following: (a) sickling of the red blood corpuscles; certain and varying numbers of the red blood corpuscles assuming a crescentic shape; (b) anemia, the hemoglobin usually averaging about 50 per cent and the total red blood corpuscles about 2,500,000 per c.c.; (c) the liver usually enlarged; (f) spleen, at first enlarged, a little later becomes fibrotic and smoother than normal; (g) trophic ulcers constantly seen; (h) heart murmur; (i) abdominal pain. Alden says the last is found in eight out of eleven published cases. while Hein and McCalla² list abdominal pain as the chief complaint.

Little is known as to the etiology of this peculiar disease. Eastland and Higgins⁴ summarized the ideas of various workers, placing the blame for the changes in the morphology of the blood on: (1) primary faulty erythropoiesis;⁵ (2) surface tension phenomena;⁶ (3) immediate action of toxic, metabolic, or infectious agents upon a racial characteristic;⁷ (4) changes in plasma;⁸ (5) anoxemia.⁹ The mechanism and the etiology remain obscure.

Since 1923 over 100 reports of sickle cell anemia have appeared in the literature. In many reported cases the sickle cell anemia was a secondary manifestation and the cause of death was certainly not the anemia. In some of these cases treatment failed to change the anemia, while the symptoms improved. Examination of healthy negroes showed as many as 16 per cent with the sickling tendency but without anemia. A study of autopsy material from the negro race by Rich¹⁰ showed 62 instances of sickling in 5,000 autopsies, in none of which was the disease suspected. Furthermore, the sickling tendency does not seem peculiar to negroes, since Cooley and Lee¹¹ describe it in a family of Greeks.

Lawrence¹² reports three cases, not all negroes, in which the morphologic changes in the red blood cells were found but in which the classical picture was not so obvious. Recently, Terry, Hollingsworth and Eugenio¹³ presented

*From the Department of Pathology, and the John C. Oliver Memorial Research Laboratory, St. Margaret Memorial Hospital.
Received for publication, March 16, 1933.

more than 50 cases showing elliptic erythrocytes without any relation to age, sex, color, or blood group, and without relation to sickle cell anemia. A complete bibliography is given by Fradkin and Schwartz. The blood findings and the physical findings so often seen offer an interesting field for further study.

The treatment of sickle cell anemia is unsatisfactory. In spite of the therapeutic measures used, the disease usually proves fatal; few of the patients in the reported cases reaching thirty years of age. Among the procedures, splenectomy has been done with varying results. The use of splenectomy is based on the hypothesis that the red blood cell destruction takes place chiefly in the spleen, and upon the results in hemolytic jaundice. However, this procedure gives no assurance of help, although it tends to relieve the excessive red blood cell destruction. Stewart,¹⁴ Bell and his associates,¹⁵ Cooley and Lee,¹¹ and Hahn,¹⁶ have reported cases in which splenectomy was done without cure but in which the excessive red blood cell destruction was lessened. Transfusions have been tried and invariably give only temporary relief. Liver therapy does not give a satisfactory response. The reasonable treatment consists of such supportive measures as generous amounts of wholesome food, rest, fresh air, and avoidance of infection, with blood transfusion and iron and arsenic to combat the anemia. Splenectomy should perhaps be advised as a last resort.

The differential diagnosis is sometimes difficult. Alden comments that tertiary syphilis obscured the diagnosis for months in one of his cases and that acute appendicitis was strongly suggested in another. Smith¹⁷ reported a case in which congenital hemolytic jaundice was the tentative diagnosis. The enlargement of the heart with murmur often leads to the diagnosis of endocarditis. Probably the symptoms and findings most commonly suggest congenital hemolytic jaundice. However, in this latter condition leg ulcers and joint pains are rare, and the spleen is always enlarged. The laboratory findings of sickle cells and a normal fragility of red blood cells confirm the diagnosis of sickle cell anemia. Syphilis is readily ruled out with serologic tests. The diagnosis rests upon consideration of the blood picture, and the typical physical findings.

CASE REPORT

J. H., a negro boy, aged ten years, was admitted to the services of one of us, with a complaint of chronic ulcer of the leg. The ulcer was situated over the left external malleolus and had been present for over a month. There was no history of trauma. In the past this boy had been considered "delicate." He could not play with other boys of his own age because of dyspnea and shortness of breath. He had no illnesses but mumps in early childhood. No family history relating to his present illness could be elicited.

Only the positive findings on physical examination will be recorded. His sclerae showed a moderate jaundice. The heart was markedly enlarged to the left, and there was a loud systolic murmur heard over the mitral area, accompanied by a thrill. The liver was enlarged four fingerbreadths below the costal margin, and the spleen was not palpable. There was a small ulcer over the left external malleolus measuring 7 cm. by 4 cm., with its long axis vertical. The ulcer showed a granulating, unhealthy base covered by exudate. The edges were slightly undermined.

THE LABORATORY FINDINGS

Urine.—In several dozen specimens albumin was constantly present. Casts appeared at intervals and pus was always present.

Blood Count.—The red blood cells ranged from 1,500,000 to 2,260,000, and the hemoglobin remained about 45 per cent. The greatest improvement was seen temporarily following transfusion. Morphology of the red blood cells showed many "sickle" cells (Fig. 1) in both wet and stained preparations. This picture remained constant throughout the disease. Poikilocytosis and anisocytosis were always noted. The white blood cells totaled always about 10,000, a terminal count showing 27,000. The polymorphonuclear cells varied as the total white blood cells. Fragility tests showed a normal range. Bleeding time was one and one-half minutes, coagulation time two minutes, icteric index 20, and the van den Bergh a positive (faint) delayed direct reaction. Wassermann and Kahn reactions were negative. Blood cultures showed no growth. Blood chemistry: nonprotein nitrogen 66 mg.; creatinine, 1.3 mg.; sugar, 90 mg.; and chlorides, 460 mg. Blood group of the patient, father, and mother were (Moss) Group IV. Cross match was without change with the father. The father had a negative Kahn test.

Throat cultures were negative on two occasions. Stool negative on four occasions.

X-ray showed enlargement of heart to the left. Lungs and mediastinum were negative.

Fig. 1.—Showing the "sickle cells."

PATHOLOGIC REPORT

Gross.—Specimen consisted of a spleen, a small lymph node, and a piece of liver. The spleen was moderately enlarged and of the usual shape. It was firm in consistency and considerable fibrous tissue was noted throughout. Here and there were round, yellowish nodules of a soft consistency. The whole spleen was purple, mottled with a large amount of yellow. The lymph node measured only $1\frac{1}{2}$ by 2 cm. and was soft and of a purple color. The small piece of liver showed nothing in the gross except that it was soft and red.

Microscopic.—Sections of spleen showed a thick, fibrous capsule. There was a large infarct, the center of which was filled with red-staining, necrotic material. Its margins were definitely fibrous and filled with chronic inflammatory cells. The pulp of the spleen was packed with red blood cells. In the interspaces were many "sickled" cells. Sections of liver showed areas of dilatation of the blood spaces. Here also were many "sickled" red blood cells. The liver cells showed everywhere clouding and granular changes in their cytoplasm. The interstitial tissue was moderately increased, and filled with chronic inflammatory cells. Sections of lymph node showed sinuses filled with blood, including many sickle cells. The follicles were small and widely separated.

Diagnosis.—White infarct of spleen, splenomegalia (sickle cell anemia), chronic hepatitis, chronic congestion of liver, hyperplasia of mesenteric lymph nodes, and chronic lymphadenitis.

TREATMENT

The treatment consisted of general measures, as rest in bed, sunlight, and nutritious food. The ulcer was treated by elevation of the part, and wet dressings, with no response. A transfusion, using the father as donor, was done. After several days some improvement in the boy's general condition, and in the anemia was noted. This improvement was only temporary and on the thirtieth day, after consultation, it was decided to do a splenectomy. The operation was uneventful, the spleen being removed without difficulty, and a wedge of liver taken. Unfortunately, postoperative pneumonia on the third day was followed by the death of the patient. Every effort to obtain an autopsy was combated by the parents.

SUMMARY

A brief review of the recent literature on sickle cell anemia is given and the outstanding symptoms and findings are outlined; the etiology being reviewed from the literature.

Sickle cell anemia being a rare and obscure disease, the treatment is largely symptomatic, and seldom successful.

The diagnosis may be made without difficulty. Too much emphasis cannot be placed upon the careful routine examination of the blood, which should include wet preparations as well as stained smears.

The case presented shows all the characteristic findings of sickle cell anemia. Transfusions and splenectomy failed to cure the patient.

THE MECHANICS OF SPLEEN VISUALIZATION BY MEANS OF METALLIC COMPOUNDS, IN PARTICULAR THORIUM*

HILLYER RUDISILL, JR., M.D., F.A.C.P., CHARLESTON, S. C., AND
EVAN SHUTE, M.D., CHICAGO, ILL.

SINCE thorium compounds such as "Thorotrast" are being increasingly used for spleen and liver visualization, we believe that all possible information as to their action and effects should be made available. Following the original reports of Radt¹ and Oka,² on the use of a colloidal thorium compound for spleen and liver visualization, we began some experimental work early in 1931 in an attempt to arrive at the exact method of visualization. The reports of these workers and R. Jaffe³ gave the impression that the reticuloendothelial cells of organs, such as the spleen and liver, took up the thorium; which element was therefore directly responsible for the x-ray visualization that was obtained.

We used approximately the same thorium preparation as these authors had suggested. The method of preparation was essentially that described by Bluhbaum, Frik, and Kalkbrenner, quoted in detail by Radt. The actual preparation of our thorium compound was done by Dr. Marberg, a biochemist at the University of Chicago. It was prepared as follows:

Freshly precipitated thorium hydroxide, prepared from 20 gm. of thorium nitrate, was washed free of electrolyte, suspended in 100 to 150 c.c. of water. The hydrosol was peptized by the addition of small amounts of normal hydrochloric acid added to the boiling suspension over a period of five hours. (Note: The use of the hydrochloric acid is a modification by Dr. Marberg, and we believe it makes a less toxic final production.) The final solution (150 c.c.) contains 20 gm. of thorium nitrate as $\text{Th}(\text{OH})_4$. This is equivalent to 9.78 gm. of thorium or 12.5 gm. of thorium hydroxide. Also equivalent to 0.0653 gm. of thorium per c.c., or 0.0833 gm. of thorium hydroxide per c.c. The solution contains 0.0643 mols of hydrochloric acid per liter. Stable at boiling and refrigerator temperatures; also stable toward addition of neutral salts and glucose.

A dog two weeks old weighing 1.4 kilo was x-rayed and showed no spleen shadow. On Feb. 21, 1931, 1 c.c. of thorium solution, plus 7 c.c. of normal saline, was injected into the anterior fontanel with no clinical ill effect. A film taken twenty-four hours later showed faint visualization of the spleen. There was excellent visualization at forty-eight hours. At ninety-six hours the spleen shadow was beginning to fade. The liver was possibly denser than the other upper abdominal viscera, but could not be definitely differentiated. On Feb. 27, 1931, the same dose of thorium solution was repeated at the same site. Thirty hours later the spleen visualization was again at its maximum. The animal was killed and autopsied Feb. 28, 1931.

*Received for publication, January 25, 1933.

Microscopic study of sections of the injected spleen showed irregular degeneration and cloudy swelling of its cells, especially adjacent to the sinuses and capillaries, the latter were crammed with thorium particles, and discrete brownish particles were scattered diffusely throughout the stroma. The corpuscles were relatively unaffected. There seemed to be no tendency for the ingestion of the particulate matter (thorium) by the reticuloendothelial cells.

We next used three dogs about two months of age but varying considerably in size. Dog 1 was a control, weighing 2,200 gm. The other dogs weighed 1,100 and 1,600 gm. respectively. All were x-rayed and showed no evidence of a splenic shadow. One cubic centimeter of a special colloidal solution of mercuric sulphite was administered intravenously to the 1,100 gm. dog. Films were taken twenty-four hours after injection and again at forty-eight hours; the spleen was not visualized. The 1,600 gm. dog was given 1 c.c. of the thorium solution plus 4 c.c. of a mixture of 10 per cent glucose and normal saline by the anterior fontanel. There was no systemic reaction. In twenty-four hours there was excellent visualization of the spleen, the shadow remaining the same density at forty-eight hours. All three dogs were killed within fifty hours from the beginning of the experiment. At autopsy the only gross change observed was in Dog 2 (the one injected with mercuric sulphite) whose spleen showed a purplish black discoloration.

Microscopically the lymphoid cells of the control spleen were normal. There were a few particles of hemosiderin here and there, but they were not dense.

The spleen of the "mercury" Dog 2 showed the cells crowded together with some swelling and pallor. There were much larger pigmented particles than the hemosiderin throughout the sections, but none of the large particles (mercuric sulphite) were inside the cells of the reticuloendothelial type. The blood vessels were filled with leucocytes and in many places contained much of this particulate material. In the spleen from the "thorium" dog there was swelling of the stroma and the cells were pale and swollen. The blood vessels showed the same type of leucocytic chemotaxis as in the "mercury" dog. The Malpighian corpuscles were not appreciably involved. No thorium had been taken up by reticuloendothelial cells but the stroma was literally peppered with thorium particles. A few macrophages were present and had ingested various quantities of thorium. Those that contained the greater quantity of thorium showed a marked degeneration.

It seemed from the above that simple cloudy swelling might prove to be an essential factor in visceral visualization of this type. Therefore, we undertook to study it in vivo. We gradually poisoned a three-month-old dog with a soluble salt of mercury (bichloride of mercury), giving $1\frac{1}{2}$ gr. a day for three days, 7 gr. on the fourth day, and 7 gr. intramuscularly on the fifth. The spleen was visualized by x-ray on the fifth day quite clearly, and also on the sixth day, but perhaps a little less distinctly. The viscera as a whole seemed to show more definitely than usual. The dog was killed on the sixth day when acutely ill with mercurial nephritis.

Microscopically the spleen showed lymphocytes that were unusually large and crowded together. In fact the cells were so pale and swollen that it was difficult to differentiate lymphocytes from reticuloendothelial cells, monocytes, and etc.

RÉSUMÉ

The method of Oka and Radt for visualizing the spleen by the administration of thorium intravenously seems to be adequate as far as x-ray findings are concerned. However, the thorium seems to produce an intense degeneration of the spleen in doses too small to give clinical signs. The thorium appears to be taken up largely by the blood sinuses and lodged in the stroma rather than in the reticuloendothelial system. Other colloidal particulate matter (mercuric sulphite) is taken up in the same way but does not produce x-ray visualization of the spleen apparently because cloudy swelling does not result.

The spleen is visualized if an acute cloudy swelling is produced as in bichloride of mercury poisoning, but this visualization is not as marked as that obtained with thorium.

CONCLUSIONS

1. Intravenous injections of thorium give satisfactory x-ray visualization of the spleen.

2. This visualization of the spleen is due in part to the thorium particles in the stroma and capillaries, but cloudy swelling seems to be also an important factor.

A STUDY OF PUNCTATE STIPPLING AS FOUND IN THE LEAD POISONING OF WILD DUCKS*

F. M. JOHNS, M.D., NEW ORLEANS, LA.

PUNCTATE or basophilic stippling of erythrocytes has apparently been a subject of controversy since it was noted by Ehrlich in 1885.¹ Stippling was first correlated with lead poisoning by Behrend some fourteen years later, in 1899.² A voluminous literature on the subject accumulated, which when summarized by Pappenheim³ in 1919, fell far short of proving the mechanism of its production, or of a clear-cut clinical conception of its significance. The toxic conditions in which stippling was found were well known; but regarding the granules themselves, opinions varied from the toxic granular degeneration theory of Pappenheim to the nuclear fragmentation theories of Kreibich⁴ and Koch.⁵ Many of our standard textbooks still quote one or the other of these theories, which, in fact, are both undoubtedly wrong.

Modern knowledge regarding this phenomenon began with Key in 1924.⁶ Working with rabbits in experimental lead poisoning he proved that the percentage of stippled cells rose and fell in direct proportion to the reticulocyte variation, and that the number of reticulocytes was approximately equal to the combined number of stippled and basophilic erythrocytes, thus proving that stippled cells were immature erythrocytes. Four years later Brookfield⁷ confirmed this finding in human subjects.

Cooke and Hill⁸ in a study of the microscopic picture of pernicious anemia state that stippling is produced by the remains of the original cytoplasm of the erythroblast; and that the reason for its taking the azur-eosin stain after fixation with alcohol may be found in a defect in the immature lipin covering of the cells. Lane⁹ shortly thereafter agreed with Cooke's hypothesis and further disproved the old theories by an ultramicroscopic (dark-field) study of stippled cells, the granules of which could not be demonstrated in wet or wet-fixed films. As all other toxic granular degeneration products or nuclear fragments can easily be demonstrated by strong indirect illumination, it seems thoroughly proved that the accumulation of basophilic staining material into clumps in certain young erythrocytes represents an alteration of the protoplasm of these cells that interferes with its ability to remain diffused throughout the cell during the process of drying.

Incidental to a survey of wild fowl in Louisiana to determine the occurrence and extent of accidental lead poisoning from ingested shot, a careful blood survey was added to the routine pathologic examination. Numerous specimens showing all degrees of stippling were encountered. The presence of nucleated erythrocytes in fowls enables a direct determination of the degree of poisoning

Received for publication, March 25, 1933.

necessary to produce stippling. The occurrence of basophilic stippling in large numbers of ducks is also of interest in view of the statement by Key⁶ that several investigators, including A. S. Minot, had been unable to produce it in chickens.

Wild duck arriving in southern Louisiana in mid-November congregate on large shallow lakes formed by inundation of former agricultural reclamation projects in the fertile marsh areas. Members of the seaup group, particularly black duck and d'eau gris, in feeding on the seeds of an aquatic plant which are about the size of ordinary lead shot, find and ingest large numbers of lead pellets

Fig. 1.—Normal blood of wild duck.

Fig. 2.—Active blood regeneration following acute blood loss in acute lead poisoning. Numerous shot present in the gizzard that had lost only a fraction of their lead content.

that have accumulated during the past few years of intensive hunting. Wetmore¹⁰ presents a clinical and experimental study of this lead poisoning, citing experiments proving that three or four No. 6 shot will usually kill a captive wild duck. An average incidence of 12 shot were found in 89 ducks of this species in this investigation, the individual variation being from 0 to 140 shot.

Duck arriving in the ponds relatively free from lead (see Fig. 1) acquire their lead in apparently a few days' feeding. Within a week, and while still able to be taken on the wing, they present all of the symptoms of an acute lead

poisoning (Fig. 2) with tremendous loss of weight, anemia, diarrhea, bile-stained mucosa of the gizzard, active hemopoiesis of the long bones of the leg and an enormous increase in the number of reticuloocytes, which may reach a total of 70 per cent of the cells in the peripheral circulation, together with large numbers of erythroblasts and megaloblasts. Those that survive this acute poisoning, as shown by the presence of numerous shot in the gizzard, and which have lost from 20 to 50 per cent of their former weight, now begin to show numerous stippled cells (Fig. 3) coincidental with unmistakable changes in the nucleus, indicating cell death. The nuclei of many of the slightly basophilic erythrocytes become swollen and pale when stained with Wright's stain. Stippling appears, the nucleus changes position to one side or one pole of the cell. In those cells with the largest basophilic granulation, the nucleus appears only as a shadow. Fragmentation of the nucleus can be observed as a terminal process in these stippled cells, the nuclear fragments staining a definite purple and the basophilic granules a deep blue with the polychrome stains. It would seem reasonably certain that the direct combination of lead with phosphates on the

Fig. 3.—Chronic lead poisoning with stippling and nuclear degeneration and fragmentation. Numerous shot present in the gizzard that had been ground down to show a loss of 3 or more grams of metallic lead.

surface of the erythrocytes and the local liberation of a weak acid, as shown by Aub, Reznikoff and Smith,¹¹ is sufficiently toxic to produce actual cell death. The original cell protoplasm, represented by the basophilic stain of the erythrocyte, is not then able to withstand even the momentary effect of still further injury in drying, but precipitates or condenses into a granular form. It is thus demonstrated that the significance of a stippled cell is that of a dying cell and not merely a young cell that may continue to mature in the circulation. This visual proof of the chemical selection and untimely destruction by lead salts of a semimature cell is direct proof that stippling is a pathologic change in the sequence of events in the usual maturation of such cells in the peripheral circulation.

LABORATORY METHODS

A NEW SYPHILIS REACTION, THE M.K.R. II IN CEREBROSPINAL FLUIDS*

ERNST MEINICKE, M.D., HAGEN-AMBROCK I. W., GERMANY

THE procedure for using the M.K.R. II in *serum examination* as now widely practiced may be briefly summarized as follows: 0.2 c.c. active serum is mixed with 0.5 c.c. of a freshly prepared suspension of the blue M.K.R. II antigen, and the test tubes are well shaken. For reading the results there is a choice of four different indicators:

1. *Macroscopic flocculation reaction*: The flocculation is read like an agglutination test after one and one-half hours with a hand lens.

2. *Microscopic flocculation reaction*: Immediately after setting up the tests drops of the reaction fluid are taken with a pipette and deposited on level slides which must be kept in a moist chamber for one hour, whereupon the reaction is read under a microscope with sixty fold magnification.

3. *Clarification reading*: The test tubes are left overnight at room temperature and the degree of clarification in each tube is then ascertained with the naked eye.

4. *Centrifugal technic*: Immediately after setting up the tests, the test tubes are centrifugalized for ten minutes. When they are taken out of the centrifuge, the supernatant fluid is carefully poured off and the tubes placed upside down in a rack. They are examined in half an hour's time to see whether the sediments have run down the sides of the tubes, or whether they have remained unaltered.

In the course of *experiments with cerebrospinal fluids* which I carried out jointly with Dr. Holthaus, it soon became apparent that the dosage of the serum test and the various methods of reading it could not be applied without some modification to the investigation of spinal fluids. Weak positive spinal fluids, in the dosage 0.2 c.c. fluid + 0.5 c.c. antigen suspension, were found to give a negative reaction. Thereupon we increased the amount of fluid, at the same time decreasing the amount of antigen, for instance: 0.5 c.c. spinal fluid + 0.1 c.c. antigen suspension. It now showed itself however that, owing to the small amount of antigen, the reaction fluid was not turbid as in the serum test, but more or less clear from the outset, so that there could be no question of applying the clarification indicator to the readings. But neither were the flocculation reading or the centrifugal technic quite satisfactory.

*Received for publication, May 2, 1933.

We were therefore under the necessity of searching for a new indicator for *spinal fluid examination*; this we eventually found in *sediment reading*. If, after setting up the tests, the test tubes are left standing overnight at room temperature, a deposit of sediment becomes visible in each tube presenting variations in the case of negative or positive reactions which are easily recognizable with the naked eye. In *negative* reactions a blue, fairly clean-cut disc-shaped sediment forms at the bottom of the tube. In *positive* reactions there is no sign of this blue disc, but the bottom of the tube is covered with a light, whitish, filmy sediment, sometimes so slight as to be only distinctly ascertainable as sediment with the help of a hand lens. *The determining factor for the appreciation of the reaction is always the presence or absence of the characteristic blue, disc-shaped sediment. If this is visible, the reaction must be marked negative; if not, the result is positive.*

TECHNIC OF THE SPINAL FLUID REACTION

1. *Reagents*.—The same M.K.R. II Standard Antigens are used as for the serum tests. Also the 3.5 per cent salt solution of the serum tests is used in this reaction; for this an absolutely pure preparation is necessary, viz.: natrium chloratum pro analysi.

2. *Pipetting the Spinal Fluids*.—Small test tubes about 8 cm. in length and as exactly as possible 1 cm. in diameter (so-called M.K.R. tubes) are used; they should be uniformly well rounded at the base. The tubes are placed in a perforated tube rack. Care must be taken that the perforations in the lower ledge of the rack be of a size which, while preventing the test tubes from falling through, leaves as much as possible of the surface of the bottom of the tubes open to examination from beneath through the holes in the rack.

The *spinal fluids* must be examined in an *active* state. It is absolutely essential that they are *thoroughly centrifugalized* so as to be entirely free of any corpuscular admixture. When the spinal fluids are sent to the laboratory from a distance, it is most important that the containers should *not be closed with cork, but with rubber stoppers*. Nonspecific reactions may sometimes be occasioned by the dissolving of certain substances during the transport when cork stoppers have been used.

Each spinal fluid is operated in 3 tubes: in the first, 0.5 c.c. fluid, in the second, 0.2 c.c., in the third, 0.1 c.c.

3. *Preparation of the Antigen Suspensions*.—The requisite quantity of standard antigen* for the tests is pipetted to the bottom of a large test tube

PREPARATION OF THE M.K.R. II STANDARD ANTIGEN

**Heart Powder*.—The antigen is made from perfectly fresh beef hearts. The hearts are freed from fat and sinews, so that the pure heart muscle is left. This is put through an ordinary meat mincer, and then the finely chopped-up heart muscle is spread out in a flat layer on glass dishes; these are placed in a drying apparatus at from 40 to 50° C. The drying is continued until the heart pulp separates from the glass in hard crusts. These crusts are completely scraped off the glass dishes with a knife, and then placed in the incubator at 37° for two days, in order to secure its being dried as thoroughly as possible. The relatively large hard crusts of the dried heart muscle are reduced to small pieces in an absolutely dry meat mincer, and are then put through a coffee mill, so that an extremely fine powder results. This is poured into dry flasks which should be well stoppered and kept in a cool room. In making the antigens, it is advisable to mix the powder of several different hearts, because the individual hearts show slight differences in their lipid content.

Ether Extraction.—Put 10 gm. of the heart powder into an Erlenmeyer flask of 100 c.c. content, or into a bottle of the same size. The glass vessel must be closed with a stopper covered with tin foil of good quality. Extract the powder first with ether and afterward with alcohol. Use exactly 70 c.c. ether to 10 gm. of powder; shake it up several times, and let the

or pointed glass vial. The tenfold quantity of 3.5 per cent salt solution is put into a second tube or vial of the same size. Antigen and salt solution are heated *separately* in a water-bath at from 57 to 58° until they have reached a *temperature of 55-56° C.* (about 10 minutes). The right temperature may be easily ascertained by means of a thermometer which has been placed at the same time in the water-bath in a vial filled with ordinary water. The level of the water in the water-bath must be 1 or 2 cm. higher than that of the salt solution in the vial in order to ensure uniform heating. If there is not a regulated water-bath at disposal, an ordinary tub may be filled with water at from 60 to 62° C. and, when the vials and control glass have been put in, left to cool down naturally to about 57° C.

After this preliminary heating of the reaction fluids, the salt solution must be poured rapidly into the vial containing the antigen, the mixture then poured back into the empty glass and back again into the antigen glass. *The mixing must be executed rapidly*, but care must be taken to avoid spilling any of the fluid during the manipulation. The freshly prepared antigen suspension is of a milky turbid bluish hue; it must be put back *at once* into the water-bath for *exactly two minutes* for *maturing*, and then utilized immediately for the tests.

In most laboratories the examination of spinal fluids will be only a fraction of the serum examinations. The antigen suspensions for sera and spinal fluids being identical, *the same antigen suspensions are of course used for both*, and it is not necessary to prepare them especially for spinal fluids.

4. *Mixing Spinal Fluid and Antigen Suspension.*—To the first tube with 0.5 c.c. spinal fluid, 0.1 c.c. antigen suspension is added; to the second with 0.2 c.c. spinal fluid also 0.1 c.c. antigen suspension, and to the third with 0.1 c.c.

vessel stand for two hours, shaking several times again during this period. Filter off the ether through an ordinary paper filter, and again add 70 c.c. of ether to the powder. Proceed then in the same way as before for two hours. Filter off the ether once more. For the third time, add 70 c.c. of ether to the heart powder. Shake up several times during the next two hours. Afterward let the vessel stand undisturbed until the following day, and then filter the ether off. On filtering the whole powder is as far as possible, put on to the filter. After the fluid has passed through to the last drop, the filter should be carefully spread out flat and placed in the incubator at 37° until the next day. The glass vessel in which there still remain traces of the powder, should likewise be placed in the incubator. By the following day, the ether will have evaporated for certain. Put the powder on the filter back again into the bottle, and begin with the alcohol extraction.

Alcohol Extraction.—Pour 80 c.c. of 96 per cent alcohol over the heart powder which has been collected as completely as possible in the glass vessel. Let the bottle stand for eight days at room temperature, thoroughly shaking it several times a day. Then filter off and keep the heart extract at room temperature.

Adding of Balsam of Tolu and Victoriablue.—Dilute 10 c.c. of the heart extract with 90 c.c. of 96 per cent alcohol and add 1.4 gm. of balsam of Tolu to this dilution. Place the bottle in the incubator at 37° for two days and shake it several times a day. Then keep it at room temperature for a week and filter off through an ordinary paper filter. After adding of 0.01 gm. of Victoriablue to the filtered Tolu-Antigen it is ready for use.

Standardization of the M.K.R. II Antigen.—The Antigen thus prepared possesses approximately the right lipid content of 1:10, requisite for the syphilis tests. In order to be able to weaken or to strengthen it, as the case may be, some balsam of Tolu in the proportion of 1.4 per cent is dissolved in the undiluted alcoholic extract which is rich in lipoids, and some also in an extract diluted 1:100 with alcohol which is extremely poor in lipoids. The addition of the undiluted extract to the M.K.R. II antigen serves to increase its lipid content and thus to weaken the sensitivity of the tests; the addition of the much diluted extract, to lower the lipid content and thus to make the tests more sensitive.

The standardization of the antigen must be performed, in testing it with positive and negative sera, according to the prescriptions for the M.K.R. II (Zentralbl. f. Bakteriöl. 125: Pt. 1, 1932). In case the results in the serum tests should be somewhat too strong, and there should be a tendency to unspecificity, the lipid content of the antigen must be slightly increased. If, on the contrary, the results are too weak, as compared with other syphilis reactions or with the results obtained with a Standard M.K.R. II Antigen, the lipid content of the antigen in question has to be somewhat reduced.

All antigens should be kept at room temperature (not in the refrigerator) in well-stoppered bottles protected from light. The extract bottles must be stoppered with corks which should be covered with tin foil of good quality. If antigens are forwarded from one laboratory to another in frosty weather, it is advisable, on their arrival, to place them first in the incubator at 37°, and only then to store them at room temperature.

spinal fluid, 0.2 c.c. antigen suspension is added. The racks are well shaken after the addition of the antigen suspension.

If it is desirable to appreciate the quantitative degree of weak and medium strong positive reactions *with great exactitude*, two further tubes may be added to the original three. To this end another tube containing 0.4 c.c. spinal fluid and 0.1 c.c. antigen suspension is inserted between the first and second, and between the second and third a tube with 0.2 c.c. spinal fluid and 0.2 c.c. antigen suspension.

5. *Reading the Results.*—The tests having been left standing overnight (sixteen to twenty-four hours) at room temperature of about 20° C., protected from cold draughts, the results are read with the *naked eye*. The investigator stands in front of a well-lighted window or an artificial source of light above his head, lifts the racks carefully, and holds them before him somewhat above his eye level, at the same time slanting them slightly forward. In this position the apertures of the test tubes are in a slanting direction to the source of light above and the base is toward the investigator.

a. *Negative Reactions:* In all three tubes *blue disc-shaped sediments* are visible in the center of the bottom of the tube, their coloring contrasting sharply with their surroundings. These blue sediments are *soft and have a tendency to dissolve*. If the rack is held in a slanting position for some little time, they will, following the law of gravitation, dissolve themselves into a thin streak. Shape, color and dissolubility of the sediments are the characteristics of a negative reaction.

b. *Weak Positive Reactions:* The first tube with 0.5 c.c. of spinal fluid does not show any blue disc-shaped sediment. The bottom of the tube is of a whitish opalescent hue. On close examination a very light filmy sediment is visible uniformly spread over the bottom of the tube. When held slanting for any length of time, this sediment does not dissolve; it will sometimes change its position as a whole, or it may crumble to pieces. Both the other tubes present the characteristic blue negative discs.

When in the first tube neither a distinct dissoluble blue disc nor the uniformly opalescent whitish coloration at the bottom of the tube is visible, the reaction must be marked *doubtful* (\pm). Then there is generally a rudiment of disc formation to be seen in the first tube with a number of minutest fragments of sediment strewn around it. In such cases the central disc is usually not soluble but adheres more or less firmly to the bottom of the tube.

c. *Medium Strong Positive Reactions:* The two first tubes with 0.5 c.c. and 0.2 c.c. spinal fluid show the positive sediment described in paragraph b., while the third tube has a negative disc.

d. *Strong Positive Reactions:* The negative blue disc is not visible in any of the tubes. They all show the connected whitish sediment of a positive reaction completely covering the bottom of the tube. In correspondence to the relatively larger amount of antigen in the last tube, the sediment in it is somewhat denser than in the first two, and may sometimes be slightly bluish in coloring.

e. *Hyperpositive Reactions:* Occasionally, though rarely, in cases of paralysis and tabes, spinal fluids may be observed which react so strongly that they

present an inhibition in the first or in both the first tubes. In these tubes more or less distinct blue negative discs have formed, while the characteristic broadly spread positive sediment appears in the last tube only. Compared to the weak positive reaction there is therefore in such cases a *reversed scale with the strongest reaction in the last tube*.

f. *Bacterially contaminated spinal fluids*, for instance, such as derive from cases of meningitis or have become decomposed during transport, may occasionally show the *same scale as hyperpositive reactions*. They must therefore be differentiated by a special test. To 0.1 c.c. of the questionable spinal fluid, 0.1 c.c. of a proved negative active serum and 0.5 c.c. of the usual antigen suspension is added. The mixture is well shaken and the reading performed in the way usually practiced in serum tests, viz.: either as macroscopic or microscopic flocculation or on the following day as clarification. *In the serum dilution contaminated spinal fluids always give a plainly negative reaction, whereas hyperpositive spinal fluids give a strong positive reaction.*

THE M.K.R. II AS COMPARED TO OTHER SPINAL FLUID REACTIONS

Our comparative investigations comprising some 600 cases have shown that the M.K.R. II applied to spinal fluids is appreciably superior in *sensitivity* to the Wassermann reaction, and is at least equal to the Kahn standard method and the Müller conglobation reaction.

Also with regard to *specificity* the M.K.R. II in spinal fluids is in no wise inferior to the above-named methods. It is a very simple method, is easily read, and provides the possibility of obtaining a good quantitative gradation of positive reactions with only three test tubes.

The M.K.R. II thus belongs to the group of particularly sensitive specific syphilis reactions in spinal fluid diagnosis as well as in serodiagnosis.

A NEW COLORIMETRIC METHOD FOR THE DETERMINATION OF BILIARY ACIDS IN BODY FLUIDS: WITH A NOTE ON THEIR ALLEGED PRESENCE IN NORMAL BLOOD*

L. D. SCOTT, LONDON, ENGLAND

SINCE the introduction of the Pettenkofer¹ reaction for the recognition of bile acids, many attempts have been made to apply this test for estimating bile acids in blood. As a result of these researches it has been assumed that a positive Pettenkofer reaction given by specially prepared extracts of normal blood is an indication of the presence of bile salts. On this assumption Aldrich and Bledsoe² found that normal blood contains bile salts to the extent of 3 to 6 mg. per 100 c.c., while Charlet's³ average findings are given as 3.5 to 3.8 mg. in normal rat blood.

On the other hand, by using different means of isolation but still using the Pettenkofer reaction, Perlzweig and Barron⁴ as well as Gregory and Pascoe⁵ deny the presence of bile salts in normal blood.

Recently Walker⁶ has called attention to the interesting and important fact that the substance responsible for the color production in the Aldrich and Bledsoe process is cholesteryl oleate. This is hydrolysed by barium hydroxide to barium oleate. The cholesteryl oleate and barium oleate both give a positive Pettenkofer reaction.

From a practical standpoint, however, it cannot be denied that nearly all the methods have the common objection in that the Pettenkofer reaction is employed. A critical study of the quantitative aspects of this reaction has revealed many undesirable features in that: (a) the color reaction is not specific for bile acids, Mylius⁷ finding 15 other substances (including barium oleate) that give a Pettenkofer reaction; (b) the quantitative recovery of bile acids is very variable with errors from 1 to 20 per cent; (c) the red or reddish color varies considerably as to color shade making comparison in the colorimeter exceedingly difficult.

It is obvious from the above results that the Pettenkofer reaction is wholly unsatisfactory for quantitative purposes even with pure solutions of bile acids, and quite unreliable even for qualitative work on body fluids.

A large number of tests have been advanced for the detection and estimation of bile salts in the urine, most of which again employ the Pettenkofer reaction, either direct to the urine, or to the isolated salts. If the reaction is applied direct to urine containing proteins a positive Pettenkofer reaction is always obtained. It hardly needs to be emphasized here that chromogenic substances yield intense colors with sulphuric acid. In the isolation method where the bile salts are precipitated from urine by saturation with magnesium sulphate,

*Received for publication, February 23, 1933.

The studies were carried out in the Bio-Chemical Laboratory, Charing Cross Hospital, Institute of Pathology, by kind permission of Dr. J. Patterson, biochemist to the hospital.

bilirubin is also precipitated along with many other urinary pigments. As bilirubin is almost always present in combination with bile salts, the color produced in the final stage of the method is entirely lost in the dark brown or blackish mass obtained by the charring action of sulphuric acid on bilirubin and other urinary pigments. This process yields but little better results than that of the direct method. It is of great importance in patients treated with drugs which are potential liver poisons to try to obtain early warning of toxic action; again in patients with subicteric tints and fevers of unknown origin a reliable and quantitative method might prove of clinical value. Comparatively little work has been done in this direction, owing, presumably, to the methods being subject to the numerous limitations already mentioned.

The work outlined here was undertaken in order to arrive at a quantitative method for estimating bile salts. Various substances other than bile salts giving a positive Pettenkofer reaction and likely to be present in blood were subjected to the new reaction and found to be completely negative. The list includes cholesterol, cephalin, glycine, lanoline, phospholipines, lecithin, taurin, and oleic acid (present as cholesteryl oleate).

The following is the principle of the method:

The urine is acidified with hydrochloric acid and saturated with solid ammonium sulphate. The bile acids are precipitated completely, along with other urinary pigments. Bilirubin when present is also precipitated. To prevent the precipitated bile salts from adhering to the sides of the boiling tube and stopper, a small amount of protein is first added to the urine before adding the hydrochloric acid and ammonium sulphate. The protein has the effect of "holding" together the biliary acids, and thus overcoming great practical difficulties in that obvious loss of material is prevented as well as rendering time-consuming efforts unnecessary. The precipitate is filtered and washed with a saturated solution of ammonium sulphate to remove any soluble adhering pigments. The filter paper is carefully dried and the bile salts plus the insoluble urinary pigments extracted with absolute alcohol. A saturated solution of barium hydroxide is added to the extract, and after further concentration the mixture is diluted to a convenient volume with alcohol, and filtered after thorough cooling. The addition of the barium hydroxide renders bilirubin and other interfering urinary pigments insoluble in absolute alcohol. The alcoholic extract is evaporated to dryness and a reddish purple color produced from the residue by the action of levulose and pure hydrochloric acid. The standard is an alcoholic solution of sodium tauroglycocholate and is similarly treated. The colors are then compared colorimetrically.

Reagents and Apparatus.—

1. Pure concentrated (A. R.) hydrochloric acid (sp. gr. 1.16) $\text{HCl} = 36.465$.
2. Pure syrupy (A. R.) phosphoric acid (sp. gr. 1.75) $\text{H}_3\text{PO}_4 = 98.051$.
3. One per cent pure levulose (Merck) in a saturated solution of benzoic acid. This keeps indefinitely.
4. Saturated aqueous solution of ammonium sulphate.
5. Solid ammonium sulphate.
6. Fresh blood serum or plasma. For the precipitation to succeed it is absolutely essential that the serum or plasma employed be perfectly fresh, and this is usually obtainable in any modern laboratory.

7. Absolute alcohol (97 per cent).

8. Filter papers: Whatman extraction thimbles, size about 22 by 80 mm., and ordinary No. 1 papers, 7, 9, and 11 cm. in diameter.

9. A saturated aqueous solution of barium hydroxide.

10. Five-tenths per cent sodium tauroglycocholate in absolute alcohol. Owing to the hygroscopic nature of the bile salts, it is important to weigh out the above amount on glazed paper, and as quickly as possible. Transfer the bile salts to a 100 c.c. flask, add about 60 c.c. of absolute alcohol and immerse the flask with constant agitation in a boiling water-bath until the bile salts have dissolved completely. Cool, and dilute to the mark with absolute alcohol. After mixing thoroughly, filter through a 9 cm. paper.

11. Preparation of asbestos mat. Use a Gooch crucible of about 15 c.c. capacity (see Fig. 1) or an asbestos mat supported on a small (15 mm. diam.) perforated porcelain plate, resting in a conical funnel that passes through a rubber stopper fitting the neck of a filtering flask. The mat is prepared as follows: A suspension of well-washed asbestos is poured into the Gooch crucible or onto the plate and allowed to settle down without suction. After a short time the filtering flask is connected to the suction pump and the water pressure turned on. It is important not to suck too hard. The amount of asbestos required is such as to form a mat about 3 mm. in depth.

Fig. 1.

A small porous plate may be placed on top of the mat to prevent the latter from being disturbed too much by pouring on water or the phosphoric acid mixture. The mat is then washed two or three times with distilled water, gentle suction being applied after each addition. The final suction should be sufficient to make the mat quite firm. After being used for filtration of the phosphoric acid mixture the asbestos should be washed well with distilled water before further use.

METHOD

For Urine.—Introduce 25 c.c. of urine into a thick-walled boiling tube (Monax combustion tubes, 1 inch by 6 inches) followed by 0.05 c.c. of fresh blood serum or plasma. After mixing with the protein solution, add 2 c.c. of pure concentrated hydrochloric acid, mix again, and then saturate the acidulated solution by the addition of 25 gm. of solid ammonium sulphate. Securely stopper the tube, and after thorough shaking, stand for about ten minutes with occasional agitation to ensure for complete saturation with the ammonium

sulphate. Filter through a Whatman No. 1, 11 cm. paper which has been previously damped with a few drops of a saturated solution of ammonium sulphate. The filtrate should be transferred back to the precipitation tube and after mixing well, filtered again. This process prevents loss of any bile salts which may have escaped through the filter paper with the first few drops of the filtrate. The filtrate can now be discarded. The filter paper and precipitation tube are then washed with about 50 to 100 c.c. of saturated solution of ammonium sulphate, transferring about 20 c.c. of this at a time to the precipitation tube and after stoppering and shaking vigorously, poured on to the filter paper. In this manner traces of bile salts adhering to the boiling tube and the stopper are removed as well as the HCl introduced in the first stage of the process. Most

Fig. 2.

of the interfering urinary pigments are also removed by this washing. The washed paper and funnel are allowed to dry overnight in the incubator at 37° C. It has been found possible to dry the filter paper containing the bile salts in a hot air oven at about 90° C. to 100° C. for one hour. The ordinary copper still oven is superior to a flame heated oven and more convenient. The dried paper containing the bile acids is carefully folded, or better still cut into small strips, and inserted into a paper extraction thimble (Whatman thimbles, 22 by 80 mm.). The salts are then subjected to steady extraction with about 25 c.c. of absolute alcohol for sixty minutes, using the modified Soxhlet extraction apparatus (see Fig. 2) recommended by Myers^s for the estimation of cholesterol in blood. An electric hot plate is used for heating and

great care must be taken not to char the solution by excessive heat. The alcoholic extract is then removed, cooled, and transferred to a 50 c.c. measuring flask, rinsing out the extraction flask with small quantities of absolute alcohol and transfer the washings to the graduated flask, until the volume reaches about 35 to 40 c.c. An alternative but not so reliable method is to place the filter paper containing the bile acids into one of the large boiling tubes and extract with about 5 c.c. portions of absolute alcohol brought to boiling point each time by immersion of the tube in the boiling water-bath. The boiling of the alcohol should be continued for two or three minutes after ebullition. The alcoholic extract is then cooled and filtered through a small 7 cm. paper into the 50 c.c. flask to remove traces of ammonium sulphate. Extraction can be discontinued when 30 to 35 c.c. of alcohol have been used. Two cubic centimeters of a saturated solution of barium hydroxide is then added, and after the addition of a few porous plate chips to prevent bumping, the flask is placed in the boiling water-bath, and the alcohol gently boiled for about three minutes when the total volume will be reduced by about one-tenth. The flask is then removed and thoroughly cooled in running water after which the volume is made up to the mark with absolute alcohol. It might be mentioned that this barium hydroxide treatment does not remove any bile salts from the alcoholic extract. Quantitative figures show an absolute recovery of bile salts.

It is essential to cool the alcoholic extract thoroughly after boiling with the barium hydroxide. If convenient the solution should be allowed to stand from one to two hours so as to allow the baryta treatment to remove the last traces of urinary pigment. A quicker process is to stand the flask in the ice chest for about one hour, or until the temperature of the mixture is round about 5° C. A convenient freezing mixture is ice and dilute sulphuric acid which gives a temperature of about -10° C. (Approximately 50 gm. ice and 60 c.c. of 25 per cent H_2SO_4 .) Another good mixture is made as follows: 10 gm. of ammonium nitrate, 10 gm. of sodium carbonate, and 10 c.c. of water. The temperature reached is about 0° C.

After mixing well, filter through a 9 cm. paper that has been previously dampened with a few drops of alcohol. Slight turbidity of the filtrate can be safely overlooked as this does not interfere with the subsequent determination.

Forty-five cubic centimeters of filtrate are measured into one of the boiling tubes, and after the addition of a few silica chips, the alcohol is evaporated to dryness on the boiling water-bath. If the boiling tube is unable to hold 45 c.c. filtrate, first evaporate 25 c.c. of extract almost to dryness and then add the other 20 c.c. of filtrate together with another silica chip to prevent bumping. Keep the water temperature of the bath from about 85° to 90° C. at the beginning of the evaporation and raise the temperature to boiling as the alcoholic solution slowly reduces in volume.

It may occasionally be found that owing to the presence of water which was introduced with the saturated barium hydroxide solution, the last traces of alcohol cannot be removed. The addition of a further 10 c.c. of alcohol will make it possible to evaporate the extract to complete dryness.

It is usual to employ two standards for the urinary process, that is, 0.20 and 0.50 c.c. of the 0.5 per cent alcoholic solution of sodium tauroglycocholate. The alcohol is removed by evaporation on the boiling water-bath.

The color production is now performed on the dried residues. One cubic centimeter of 1 per cent levulose is added to each of the standards and to the unknown residue, and after agitating each tube to break up the precipitate and facilitate solution, 9 c.c. of pure concentrated A.R. hydrochloric acid is then added to all three tubes. After mixing thoroughly, the tubes are securely stoppered and placed in a water-bath for thirty minutes at 38° C. Occasional agitation of the tubes is recommended to ensure an even emulsion and production of color. If bile salts are present a reddish purple color slowly develops which is characterized by a beautiful greenish blue fluorescence. After thirty minutes when the colors have reached a maximum depth, the tubes are removed from the water-bath and cooled in running water. The unknown solution is filtered through a 9 cm. paper, and if the standards are cloudy (and this is always experienced with the stronger standards) they also must be filtered. Select the standard that is nearest the unknown solution by naked eye observation, and then compare in the colorimeter immediately, as fading occurs on standing. As a supplement to the method introduced above, a technic based upon the color production from phosphoric acid and levulose has been utilized. Exactly the same technic of color production is adapted as in the former method, namely, 1 c.c. of 1 per cent levulose and 9 c.c. of pure concentrated A.R. phosphoric acid, but heating is continued for one hour at 38° C. This latter technic, although not so delicate as the hydrochloric acid method somewhat compensates for this drawback, in that the color production is quite stable and also develops to double or even treble the intensity of the original color on standing twenty-four hours. The precipitate in the unknown solution is slightly more difficult to remove with the phosphoric acid method and requires filtration through an asbestos mat in a Gooch crucible (see Fig. 1). A test tube is placed in the pressure flask to collect the filtrate. This may have to be refiltered before it is absolutely clear for colorimetric comparison. The hydrochloric acid treatment will, however, be found to be the more convenient for rapidity of strong color production.

For the experimental work portions of the alcoholic sodium tauroglycocholate of known concentration were measured into the boiling tubes and evaporated to dryness on the boiling water-bath. After the addition of heavily pigmented urines, rich in chromogens and uroerythrin, pure bilirubin was also added in large quantities. The urines were then subjected to the method given above. The results are recorded in Table I and shows the method to be strictly quantitative.

In cases when the estimation of bile salts in test meal (duodenal fluids) samples is necessary, or for the estimation of bile salts in gallbladder bile, the urine technic can be applied after suitable dilution of the specimens, although a direct method of extraction with alcohol is quicker.

Lyon⁹ has claimed that it is possible to obtain fractions after the administration of magnesium sulphate which corresponds to the bile, A from the bile

TABLE I

OBSERVED COLORIMETRIC FINDINGS OF STANDARD SOLUTION OF VARYING CONCENTRATIONS OF BILE ACID ADDED TO URINE, AND ALSO THE RECOVERY OF THE NATURAL BILE ACIDS FROM ICTERIC URINES

SERIES	OBSERVATIONS ON URINE EXAMINED	HAY'S TEST	TYPE OF REACTION	SOD. TAURO-GLYCO-CHOLATE ADDED IN MG.	RECOVERED VALUES IN MG.	CORRECTION FOR MG. PER CENT

ducts, B from the gallbladder, and C from the liver, but other workers do not agree that the bile from these three sources can be fractionated successfully. The most important part of the analysis is the bilirubin and bile salts fractions.

Chiray and Lebon state that with bilirubin and bile salts there may be little or nil in obstructive jaundice, but an increase in familial jaundice, chronic splenomegalic icterus, hemolytic jaundice, paroxysmal hemoglobinuria and pernicious anemia. In catarrhal jaundice the concentration of bilirubin and bile salts may be normal, but the total output low. There may be an increase or decrease of bile salts in parallel with bilirubin, or there may be "dissociation" as in hemolytic jaundice (see Chiray and Lebon's book, *Le Tubage Duodenal*, 1924).

In the above book Carnot and Mauban describe a technic employing Hay's test¹⁰ and have thereby obtained an approximate measurement. The new process is introduced to give a strictly quantitative method.

With test meal samples dilute 2 or 5 c.c., depending upon the icteric tint of the specimen, to 25 c.c. with water and proceed as for the urine process. For the direct extraction add the above amount of gastric juice into about 30 c.c. of alcohol, add a few porous chips and heat on the water-bath for two or three minutes. After cooling, dilute to 50 c.c. with alcohol. Filter through a 9 cm. paper. Forty-five cubic centimeters of filtrate are pipetted into a 100 c.c. capacity Erlenmeyer flask, 3 c.c. of the saturated solution of barium hydroxide are added plus a few porous chips, and the mixture is gently boiled on the boiling water-bath for about three minutes after which it is thoroughly cooled in running water. Now transfer it to a small measuring cylinder and make up the total volume of the mixture to 45 c.c. with alcoholic washings from the Erlenmeyer flask. Filter through a 9 cm. paper. Forty cubic centimeters of alcoholic filtrate are pipetted into a boiling tube, and after the addition of a few silica chips, evaporated to dryness on the water-bath. The color production is exactly the same as for the urinary process. The standard usually employed is 1 c.c. of the 0.5 per cent standard solution.

For Gallbladder Bile.—Twenty-five cubic centimeters of 1 in 100 dilution of gallbladder bile is treated exactly as for the urinary process. With the direct extraction 0.25 c.c. of pure bile is added by means of a blood pipette to about 30 c.c. of alcohol, after which the test meal method for the direct extraction of bile acids is followed. Two cubic centimeters of the 0.5 per cent solution is used as standard.

The strength of the color production is reported in terms of milligrams of tauroglycocholate for each 100 c.c. of urine, calculated by the formula:

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \frac{\text{Strength of standard (1 or 2.5 mg.)}}{\text{Amount of urine used (25 c.c.)}} \\ \times \text{Fraction used } \left(\frac{50}{45} \right) \times 100 = \text{mg. of bile salts per 100 c.c. of urine.}$$

Interpretation of Results.—An interesting fact emerges from this reaction, namely, the difference in color reaction from urinary extracts may be due to two distinct types of bile salts, Types A and B.

With Type A, the reaction is the usual response always obtained from all other body fluids, viz., no production of color in the cold, but a gradual development of color reaching a maximum in thirty minutes on warming in the water-bath at 38° C.

With Type B, the production of color begins immediately or after a few minutes in the cold, depending upon the amount of bile salts present. This coloration either develops slowly or fades entirely on heating. It is suggested that the B type of bile salts are exceedingly unstable with the result that the color development fades rapidly on heating. When, however, there is a combination of these two types of bile salts it will be observed that the color pro-

duced in the cold appears to develop on heating. The explanation may be that the B type of bile salts is stabilized by the presence of the A type, or again, on heating, the color developed from the A type of bile salts entirely obscures the fading of the color from the B type.

To overcome this difficulty the color that develops in the cold should be allowed to stand a further fifteen minutes, and after filtration compared in the colorimeter against a suitable standard prepared by heating at 38° C. in the usual way. The other process can be used by which the color can be stabilized, namely, the utilization of the phosphoric acid technic. This method will have to be adopted for all specimens of urine, as, of course, it is impossible to know when a direct production will be obtained, or again, if this coloration will develop or fade on incubation. But as already stated the phosphoric acid technic is not so convenient as the hydrochloric acid treatment, in that with the majority of urines containing small amounts of bile salts, the specimens must be allowed to stand for twenty-four hours until sufficient color has developed for colorimetric comparison.

The new reaction also disagrees with Hay's test for bile salts. This is to be expected as Hay's test depends on a lowered surface tension of the urine, and therefore is not specific for bile acids. It has been observed that substances lowering the surface tension may occur in certain cases of nephritis. Urines examined from interstitial and acute nephritis and giving a positive Hay's test show the characteristic reaction of the B type of bile salts.

Therefore, it must be concluded, by the new reaction proving these so-called "substances" to be bile salts, that the nephritic toxemias cause derangement of hepatic function. Recapitulating, it may be said that the B type of bile salts do not react to give the characteristic hydrochloric acid levulose-colored compound, and also, the majority of these bile salts remain in the filtrate from the urine and are therefore not precipitated with hydrochloric acid and ammonium sulphate. It is quite possible that the latter part of the theory given below explains these interesting findings.

The difference in the color reaction may depend either upon some slight variation in the bile salt molecule, or upon bile salts being present in some sort of association with cholesterol or a urinary constituent, which might well modify their physical properties.

Another interesting fact is that the cholesterol in the gallbladder is kept in solution as an emulsoid colloid as a result of the solvent action of bile salts. With deranged hepatic function the close association of cholesterol and bile acids makes the above theory feasible.

These are the observed facts, and it is idle to speculate as to their meaning until more is known of the physiology of the subject.

For Blood.—Into a 50 c.c. measuring flask containing about 30 c.c. of absolute alcohol, add 5 c.c. of whole blood, serum, or plasma. Immerse the flask in the boiling water-bath with constant agitation for two or three minutes, cool, and dilute to the 50 c.c. mark with alcohol. The protein precipitate should be allowed to separate roughly before filtering as this saves considerable time with filtration. The supernatant fluid is then filtered through a 9 cm. paper.

Transfer 40 c.c. of filtrate to a 100 c.c. Erlenmeyer flask, add 1 c.c. of saturated solution of barium hydroxide, and after adding a few small porous chips place in the boiling water-bath for about two minutes. The mixture is thoroughly cooled, transferred to a measuring cylinder and the volume made up to 40 c.c. with alcoholic washings from the Erlenmeyer flask. After filtering through a 9 cm. paper, 35 c.c. filtrate are pipetted into a boiling tube, a few silica chips are added, and the alcoholic extract is taken to dryness on the boiling water-bath. If frothing takes place toward the end of the evaporation this can be prevented by the addition of one or two drops of caprylic alcohol. The standard is prepared by taking 5 c.c. of a 0.005 per cent solution of sodium tauroglycocholate (1 c.c. of 0.5 per cent solution diluted to 100 c.c. with absolute alcohol) to dryness on the water-bath.

The colors are produced in a volume of 2.5 c.c., i.e., 0.25 c.c. of 1 per cent levulose and 2.25 c.c. of strong concentrated hydrochloric acid. The "unknown" solution is too small to be filtered and must be transferred to a centrifuge tube, and after securely stoppering the tube, centrifuge at high speed. Although by centrifuging the supernatant fluid never becomes absolutely clear this does not annul the delicacy of the reddish purple coloration. The unknown solution is then compared against the standard color in a similar tube by naked eye observation. If the unknown color is stronger than the standard solution it must be diluted with pure concentrated A.R. hydrochloric acid until the colors match. On the other hand if the standard solution is the stronger color, it must be diluted likewise with the hydrochloric acid. The volumes of both the solutions are now taken. This process must be called simply "an estimation," and not a quantitative determination.

$$\frac{\text{Volume in centrifuge tube of unknown solution}}{\text{Volume in centrifuge tube of standard solution}} \times \frac{\text{Strength of standard in mg.}}{\text{Amount of blood used}}$$

$$\frac{50}{35} \times 100 \text{ equals mg. of bile acids per 100 c.c. of blood.}$$

There can be little doubt that a mechanism for the manufacture of bile salts exists in the living body. In the presence of a biliary fistula such salts are continually excreted which would be impossible but for their endogenous formation. Moreover, those bile salts excreted into the duodenum are re-absorbed lower down in the intestinal tract, for none can be detected in the feces. They must therefore be circulating in the portal circulation and unless picked up quantitatively by the liver must circulate in the general blood stream and should therefore be detectable. Although some of the workers quoted earlier were unable to demonstrate the presence of bile salts in normal blood, it is by no means justifiable to conclude that they are absent. The results recorded in Table II clearly show that small quantities of bile salts added to normal blood in vitro could not be recovered. In fact on the average 5 mg. of bile salts were always lost, whatever the quantity added to 100 c.c. of blood. Lesser quantities were completely lost. It is assumed that they were carried down with the protein precipitate on the addition of alcohol, though in what form it is difficult to say. It may be possible that the bile salts are in combination with one of the constituents of the protein precipitate in which form

they actually circulate in the blood stream. Or again, the blood proteins may possess the property of "adsorbing" a certain quantity of the bile salts after which these cannot be redissolved by the absolute alcohol. This seems most likely as the ratio between bile salts and blood protein per 5 c.c. of blood is 0.25 and 350.0 mg. respectively. The amount of bile salts lost varies slightly with the total protein content of the blood.

Transfer 40 c.c. of filtrate to a 100 c.c. Erlenmeyer flask, add 1 c.c. of saturated solution of barium hydroxide, and after adding a few small porous chips place in the boiling water-bath for about two minutes. The mixture is thoroughly cooled, transferred to a measuring cylinder and the volume made up to 40 c.c. with alcoholic washings from the Erlenmeyer flask. After filtering through a 9 cm. paper, 35 c.c. filtrate are pipetted into a boiling tube, a few silica chips are added, and the alcoholic extract is taken to dryness on the boiling water-bath. If frothing takes place toward the end of the evaporation this can be prevented by the addition of one or two drops of caprylic alcohol. The standard is prepared by taking 5 c.c. of a 0.005 per cent solution of sodium tauroglycocholate (1 c.c. of 0.5 per cent solution diluted to 100 c.c. with absolute alcohol) to dryness on the water-bath.

The colors are produced in a volume of 2.5 c.c., i.e., 0.25 c.c. of 1 per cent levulose and 2.25 c.c. of strong concentrated hydrochloric acid. The "unknown" solution is too small to be filtered and must be transferred to a centrifuge tube, and after securely stoppering the tube, centrifuge at high speed. Although by centrifuging the supernatant fluid never becomes absolutely clear this does not annul the delicacy of the reddish purple coloration. The unknown solution is then compared against the standard color in a similar tube by naked eye observation. If the unknown color is stronger than the standard solution it must be diluted with pure concentrated A.R. hydrochloric acid until the colors match. On the other hand if the standard solution is the stronger color, it must be diluted likewise with the hydrochloric acid. The volumes of both the solutions are now taken. This process must be called simply "an estimation," and not a quantitative determination.

$$\frac{\text{Volume in centrifuge tube of unknown solution}}{\text{Volume in centrifuge tube of standard solution}} \times \frac{\text{Strength of standard in mg.}}{\text{Amount of blood used}} \\ = \frac{50}{35} \times 100 \text{ equals mg. of bile acids per 100 c.c. of blood.}$$

There can be little doubt that a mechanism for the manufacture of bile salts exists in the living body. In the presence of a biliary fistula such salts are continually excreted which would be impossible but for their endogenous formation. Moreover, those bile salts excreted into the duodenum are re-absorbed lower down in the intestinal tract, for none can be detected in the feces. They must therefore be circulating in the portal circulation and unless picked up quantitatively by the liver must circulate in the general blood stream and should therefore be detectable. Although some of the workers quoted earlier were unable to demonstrate the presence of bile salts in normal blood, it is by no means justifiable to conclude that they are absent. The results recorded in Table II clearly show that small quantities of bile salts added to normal blood in vitro could not be recovered. In fact on the average 5 mg. of bile salts were always lost, whatever the quantity added to 100 c.c. of blood. Lesser quantities were completely lost. It is assumed that they were carried down with the protein precipitate on the addition of alcohol, though in what form it is difficult to say. It may be possible that the bile salts are in combination with one of the constituents of the protein precipitate in which form

well. After adding a few porous chips immerse the tube in the boiling water-bath for two to three minutes, cool, and dilute to 50 c.c. with absolute alcohol. Allow the precipitate roughly to settle and then carefully pour off supernatant extract on to a 9 cm. paper. Transfer 40 to 45 c.c. of filtrate to a 100 c.c. capacity Erlenmeyer flask, add 2 c.c. of the saturated solution barium hydroxide plus a few porous chips. Heat on the boiling water-bath for about three minutes or until the mixture has concentrated about one-tenth. After thoroughly cooling the solution in running water, make up to the original volume (viz. 40 or 45 c.c.). Filter through a 9 cm. paper. Pipette 35 or 40 c.c. of filtrate into a boiling tube together with a few silica chips, and evaporate to dryness on the water-bath.

It will be noticed that the fecal residue contains much more pigment than either the urine or the blood extracts, but this does not annul the subsequent color production as the pigments and fats are rendered insoluble by the hydrochloric acid introduced in the color production stage of the method. The

TABLE III

SHOWING EFFECT OF BILE ACIDS ADDED TO FECES AND THEIR SUBSEQUENT RECOVERY

SERIES	OBSERVATIONS ON FECES EXAMINED	SOD. TAURO- GLYCO- CHOLATE ADDED IN MG.	RECOVERED VALUES IN MG.	CORRECTION FOR MG. PER CENT IN WET FECES		CORRECTED FOR DRY WEIGHT	
				THEORET- ICAL	FOUND	THEORET- ICAL	FOUND
1	Normal feces. Two grams wet feces used. Solid material 30.00 per cent	5.0	4.4	250.0	220.0	833.0	733.0
2	Normal feces. Three grams wet feces used. Solid percentage 14.30	5.0	4.7	166.6	156.6	1650.0	1095.0
3	Gross diarrhea. Three grams wet feces used. Solid percentage 8.33. Bilirubin present to extent of 93 units per 100 gm. of dry feces	--	2.1	--	70.0	--	840.0

insoluble fats and pigment are then removed by filtration. Two standards should be prepared 0.2 and 0.5 of the 0.5 per cent standard solution. The color production is the same as for the urinary process.

Calculation:

$$\frac{\text{Standard reading}}{\text{Unknown reading}} \times \frac{\text{Strength of standard in mg.}}{\text{Amount of feces taken}} \times \frac{50}{35} \text{ (or the amount of alcoholic extract finally taken to dryness)} \times 100 = \text{mg. of sodium tauroglycocholate per 100 gm. of wet feces.}$$

To obtain the solid percentage of the feces examined, weigh out exactly 1 gm. of wet feces into a small porcelain dish and dry by means of a boiling water-bath and vacuum desiccator. The weight of the remaining residue multiplied by 100 gives the solid material expressed in percentage. Now if the amount of bile salts present in 100 gm. of wet feces is multiplied by:

$$\frac{100}{\text{Solid percentage of feces}},$$
 the percentage of bile salts per 100 gm. of dried feces will be ascertained.

The present investigation proves definitely that the blood is able to conceal a small quantity of bile salts so that they escape detection. Those workers, therefore, who found bile salts absent in normal blood, actually found only their absence above a certain concentration, i.e., 5 mg. per 100 c.c. of blood. Whatever the amount of blood used the amount of bile salts carried down by the protein precipitate remains proportionally constant, viz., 5 mg. per 100 c.c. of blood. Furthermore, with methods employing a latter stage in the alcoholic extract, such as the addition of morite to remove coloring matter, a large quantity of bile salts are also removed. No matter what method is used to isolate the bile salts (and extraction with alcohol is by far the most successful), a small amount of bile acids is lost in the albuminous precipitate, which again varies considerably with the protein precipitant.

With a view to recovering the bile salts from the protein precipitates various methods were tried, such as, first the drying of blood on filter paper and extracting with absolute alcohol in the modified Soxhlet apparatus for one or two hours. Second, blood protein was removed by precipitation with absolute alcohol and then collected and subjected to steady extraction with absolute alcohol in the Soxhlet extraction apparatus from two to three hours. The results were negative in those samples to which bile salts had been added to the extent of 5 mg. per 100 c.c. of blood, as well as in bloods to which no bile salts were added.

Finally, investigation showed that even if the alcoholic extracts from very pale serums containing added bile salts (0.25 mg. per c.c. of blood) were taken direct to dryness and not subjected to the barium hydroxide treatment (there being practically no coloring matter to remove) absolute-negative results are obtained. In the above experiments the color production was performed in a total volume of 2.5 c.c., i.e., 0.25 c.c. of levulose and 2.25 c.c. of concentrated hydrochloric acid. The technic employed for the blood process is more useful as a qualitative than a quantitative method, first, because a reaction is only obtained when the amount of bile salts in the blood rises above 5 mg. per 100 c.c., and second, because a measurable color reaction cannot be obtained with quantities of blood less than 5 c.c. However, large quantities of blood can be used if available. An excess of bile acids can easily be demonstrated in the blood and the method is therefore very satisfactory.

With latent jaundice the test is rather unsatisfactory due presumably to the "holding back" of the bile acids in the protein precipitate. Here the estimation of bilirubin is superior. Further work, however, may give interesting results in connection with dissociated jaundice, i.e., independent retention or excretion of bile pigments and bile salts.

Hemolytic jaundice is certainly a dissociated condition, since the bile salts are unaffected. Retention of bile salts alone has been observed in the later stages of catarrhal jaundice.

For Feces.—Weigh out 2 gm. of wet feces with the aid of a glass rod, into one of the thick-walled boiling tubes that has been previously graduated at 50 c.c. If the feces is exceptionally liquid 3 gm. can be used. Add about 30 c.c. of alcohol and break up as much of the solid material as possible by stirring

containing 3 holes. Into one hole is fitted a thermometer; into the other 2 holes glass tubes are inserted. A piece of rubber tubing 15 to 18 cm. long is attached to one of the tubes on the inside surface of the stopper so that the circulation in the animal chamber produced by raising or lowering Bottle *A* will be efficient. Bottle *A* is filled with water and a small amount of copper sulphate introduced. If an antiseptic is not added to the water, the viscosity will be changed by bacterial growth, thus altering the emptying time of the bottle. The absorption bottles are filled two-thirds full with soda lime.* A suitable basin, either glass, galvanized iron or copper, measuring about 45 by 20 by 20 cm. is obtained and filled one-half full with water so that the animal chamber containing the guinea pig can be immersed when a determination is being made. This prevents sudden changes in the temperature of the air within the animal chamber. The walls of this basin should be painted black so that by placing cardboard or paper over the top, the animal is confined in a darkened chamber. This is an important factor in eliminating movement. The animal chamber should be anchored in the water basin and balanced in such a way that movement of the animal can be detected without admitting light to the water-bath.

The stoppers are fitted with glass tubing and the proper connections (see Fig. 1) made with a good grade of rubber tubing with fairly thick walls. The stoppers which need not be removed are sealed tightly with glue and all rubber to glass connection reinforced with wire. The rate of the flow of water from the "lift" Bottle *A* to Bottle *B* is regulated by the distance the "lift" Bottle is raised or lowered from the level of Bottle *B*. It should be regulated so that one bottle empties in exactly two or two and one-half minutes. Bottle *A* may be raised and lowered either by hand or by motor.

The system *must* be air tight. It is tested for leaks by inserting the stopper in the animal chamber, filling the spirometer with air and placing a 100 gm. weight on top of the spirometer. With Bottle *B* empty, the volume of gas in the spirometer is noted and Bottle *A* raised. When empty, it is lowered, and after Bottle *B* is again empty, the volume of gas in the spirometer is noted. If the volume of gas in the spirometer is the same as before the test, there should be no leaks, providing the temperature within the system is unchanged. Until one is convinced that the apparatus does not leak, a further test for leaks should be made after each metabolic determination by placing a weight on the spirometer with the water level in Bottles *A* and *B* stationary. The loss in volume within the spirometer should be no greater than the consumption of oxygen by the animal.

Method of Determination of Metabolic Test.—After immersing the animal chamber containing the guinea pig in the water-bath, the spirometer is filled with oxygen and the gas circulated for four or five minutes by raising and lowering Bottle *A*. After Bottle *B* is completely empty, the menisci in the inner and outer cylinders of the spirometer are adjusted to the same level and the volume of gas in the graduated cylinder, and the time noted. The temperature in

*We use Wilson's soda lime which is so extensively and satisfactorily used in determining the metabolic rate in human beings.

A SIMPLE AND INEXPENSIVE APPARATUS FOR THE DETERMINATION OF THE METABOLIC RATE IN GUINEA PIGS*

W. H. COLE, M.D., AND N. A. WOMACK, M.D., ST. LOUIS, MO.

WE WISH to present the details of an apparatus for the determination of the basal metabolic rate in guinea pigs, not because of any originality connected with its construction, but because of its simplicity and inexpensiveness. Several different types of apparatus were tried, but it required several weeks of experimentation with each to learn that, at least in our experience, the results became more constant as we simplified the apparatus. For animals as small as guinea pigs, we feel quite certain that the "closed system" type of apparatus is more practical than any other. All of the articles of glassware, etc., used in the construction are so simple that they can be found or constructed in almost any laboratory.

Description of Apparatus.—Two large glass bottles with a capacity of 2,300 c.c. to 2,500 c.c., like those used for containers of sulphuric acid, are fitted with rubber stoppers, and a hole about 2 cm. in diameter is bored in the bottom of each (see Fig. 1). One of these bottles (*B*) is fixed to a tripod on a table and the other (*A*) suspended with a cord over a pulley so that it can be lowered or raised. A thermometer is inserted through a hole in the stopper of the stationary bottle (*B*). Two bottles of about 500 c.c. capacity (to be used as absorption bottles) having large openings at the top are fitted with rubber stoppers, and a glass tube inserted through one of the holes in the stopper down to the bottom of each bottle. A small cage of wire screen is constructed and placed in the bottom of each bottle so as to prevent the hole of the tube from blocking with soda lime. A hole about 2 cm. in diameter is bored in the bottom of a 500 c.c. graduated cylinder and by means of a small pulley the cylinder is suspended into a larger glass cylinder measuring 45 cm. in height and 7 cm. in diameter. This serves as a spirometer. This latter cylinder is filled nearly to the top with water. A piece of glass tubing is bent in a narrow U-shaped fashion and anchored on the rim of the outer cylinder of the spirometer. The arm of the U-tube which is placed within the graduate cylinder is made long enough to protrude beyond the water level. The current of gas passing through this tube and out the top of the spirometer or vice versa, insures adequate circulation of the gas within the spirometer. A three-way glass stopcock is inserted between the spirometer and Bottle *B* so that oxygen may be introduced into the spirometer at the beginning of the metabolic test. A bottle with a capacity of about 1,500 c.c. and having a large hole in the top is used as the animal chamber (*F*). This jar is fitted with a rubber stopper

Received for publication, March 15, 1933.

containing 3 holes. Into one hole is fitted a thermometer; into the other 2 holes glass tubes are inserted. A piece of rubber tubing 15 to 18 cm. long is attached to one of the tubes on the inside surface of the stopper so that the circulation in the animal chamber produced by raising or lowering Bottle A will be efficient. Bottle A is filled with water and a small amount of copper sulphate introduced. If an antiseptic is not added to the water, the viscosity will be changed by bacterial growth, thus altering the emptying time of the bottle. The absorption bottles are filled two-thirds full with soda lime.* A suitable basin, either glass, galvanized iron or copper, measuring about 45 by 20 by 20 cm. is obtained and filled one-half full with water so that the animal chamber containing the guinea pig can be immersed when a determination is being made. This prevents sudden changes in the temperature of the air within the animal chamber. The walls of this basin should be painted black so that by placing cardboard or paper over the top, the animal is confined in a darkened chamber. This is an important factor in eliminating movement. The animal chamber should be anchored in the water basin and balanced in such a way that movement of the animal can be detected without admitting light to the water-bath.

The stoppers are fitted with glass tubing and the proper connections (see Fig. 1) made with a good grade of rubber tubing with fairly thick walls. The stoppers which need not be removed are sealed tightly with glue and all rubber to glass connection reinforced with wire. The rate of the flow of water from the "lift" Bottle A to Bottle B is regulated by the distance the "lift" Bottle is raised or lowered from the level of Bottle B. It should be regulated so that one bottle empties in exactly two or two and one-half minutes. Bottle A may be raised and lowered either by hand or by motor.

The system *must* be air tight. It is tested for leaks by inserting the stopper in the animal chamber, filling the spirometer with air and placing a 100 gm. weight on top of the spirometer. With Bottle B empty, the volume of gas in the spirometer is noted and Bottle A raised. When empty, it is lowered, and after Bottle B is again empty, the volume of gas in the spirometer is noted. If the volume of gas in the spirometer is the same as before the test, there should be no leaks, providing the temperature within the system is unchanged. Until one is convinced that the apparatus does not leak, a further test for leaks should be made after each metabolic determination by placing a weight on the spirometer with the water level in Bottles A and B stationary. The loss in volume within the spirometer should be no greater than the consumption of oxygen by the animal.

Method of Determination of Metabolic Test.—After immersing the animal chamber containing the guinea pig in the water-bath, the spirometer is filled with oxygen and the gas circulated for four or five minutes by raising and lowering Bottle A. After Bottle B is completely empty, the menisci in the inner and outer cylinders of the spirometer are adjusted to the same level and the volume of gas in the graduated cylinder, and the time noted. The temperature in

*We use Wilson's soda lime which is so extensively and satisfactorily used in determining the metabolic rate in human beings.

Bottle *B* and the animal chamber is recorded. Bottle *A* is immediately lowered. The distance Bottle *A* is lowered or raised is adjusted so that the bottle will empty and fill in exactly five minutes. A record of the amount of oxygen consumed is thereby obtained every five minutes. It is necessary to continue the determination for at least twenty minutes so that any errors in reading gas volume, temperature, etc., are minimized. It is very important that gas

Fig. 1.—*A*, "Lift" bottle. *B*, Stationary bottle. *C*, *C'*, Absorption bottles containing soda lime. *D*, Graduated inner cylinder of spirometer. *E*, Outer cylinder of spirometer. *F*, Animal chamber. *G*, Water-bath. *H*, Three-way stopcock.

volume in the spirometer be recorded only when Bottle *B* is empty. If water is flowing from Bottle *A* to *B* or vice versa, the pressure required to move the water is sufficient to change the volume of gas in the spirometer. By recording the amount of oxygen consumption every five minutes, it is possible to detect errors which are brought about by movement, change in temperature, leaks, etc. At the end of the determination the temperature in the animal chamber and Bottle *B* is again recorded.

Before the volume of gas is reduced to 0° C. and 760 mm. pressure, adjustment must be made for any change in temperature within the system while the determination was being made. To make this correction, it is necessary to know the volume of the various components of the system. For every degree variation in temperature, an addition or subtraction of 0.004 c.c. for each cubic centimeter of gas in the system must be made, depending on whether the temperature rises or falls. It is probably more accurate to calibrate the system. To do this all draughts are eliminated from the room, and the temperature of the air within the bottles of the apparatus as well as the room must have been constant for at least thirty minutes before the calibration is made. The temperature of the water-bath containing the animal chamber is then raised 1° or 2° by the addition of hot water to the water-bath. To be accurate, an object approximately the size of a guinea pig, should be placed in the animal chamber before this calibration is made. The change in volume of air within the system for each degree change of temperature within the animal chamber is easily determined. In our apparatus 1° rise in temperature within the animal chamber produced an increase of 5.9 c.c. in the volume of the system as recorded by the spirometer. With the temperature of the animal chamber constant, a current of heated air is turned on Bottles A and B until the temperature has reached a constant temperature. With our apparatus a rise of 1° in the temperature of Bottle B caused an increase of 13.6 c.c. in the volume of the system as recorded by the spirometer.

Sample determination: Wt. of guinea pig 450 gm. Bar. Pr. 736 mm. Hours' starvation eighteen.

SPIROMETER READING	TIME		TEMPERATURE	
236	11:50	ANIMAL CHAMBER Bottle <i>B</i>	BEFORE	AFTER
206	11:55		27.6°	27.3° (drop of 0.3°)
176	12:00		27.3°	27.2° (drop of 0.1°)
145	12:05			
114	12:10			
<hr/> 122 c.c.				

Oxygen consumption in 20 minutes = 122 c.c.

Correction for drop in temperature in animal chamber $- 0.3 \times 5.9 = 1.77$ c.c.

Correction for drop in temperature in Bottle B. $0.1 \times 13.6 = 1.36$ c.c.

Total 3.13 c.c.

Oxygen consumption in 20 minutes (corrected) = $122 - 3 = 119$ c.c.

Oxygen consumption in 1 hour = 357; at 0° and 760 mm. = 304.5 c.c.

Oxygen consumption per kilo per hour = $\frac{304.5}{450} = 676$ c.c.

As long as the weight of the animal remains approximately the same, we find it more convenient and just as accurate to record the oxygen consumption in cubic centimeters per kilo per hour, instead of cubic centimeters or calories per square meter per hour. We feel that this method is just as accurate, especially when one considers that the shape of individual guinea pigs does not vary as it does in human beings. We do find it more accurate, however, to establish an average metabolic rate for each animal by making determinations every other day for several days, and to use that average as the metabolic

rate for that particular animal, since it is true that the metabolic rate of one animal may vary 10 or 12 per cent (see Table I) from that of another.

We have listed below a series of 10 animals upon which determinations were performed during the summer months and another series of 10 with determinations made during winter months. The figures represent an average of from 4 to 8 determinations upon that particular animal. The animals listed below represent consecutive experiments, except that out of each series of 10, one animal was discarded because of exceptionally high rate caused by uncontrollable motion of the animal.

TABLE I

METABOLIC RATE c.c. per kilo per hour	
10 ANIMALS IN SUMMER	10 ANIMALS IN WINTER
640	706
675	714
663	702
635	715
634	635
666	640
600	626
581	610
621	758
635	714
Average 635 c.c.	Average 682 c.c.
Variation of -6 to +8 per cent from the average	Variation of -9.5 to +11 per cent from the average

From the figures in the above table it will be observed that the average metabolic rate was approximately 7 per cent higher in winter than in summer. The individual variation was slightly greater in winter than in summer.

No attempt was made to weigh the various foods given the animals, but it is important that the diet is not deficient in certain necessary constituents. In our experience, feeding lettuce, carrots, oats, and alfalfa, would maintain a healthy normal guinea pig.

It is essential that animals of relatively the same age and weight be used. We have had the most consistent results with guinea pigs weighing between 400 and 480 gm. Any sudden loss of weight due to starvation or illness will lead to erroneous results (elevation of the metabolic rate).

We have made many determinations using a preliminary subcutaneous injection of 7 or 8 mg. sodium amytal twenty minutes before the test, and as far as we could determine obtained accurate results. The average oxygen consumption in consecutive animals receiving sodium amytal was 608 c.c. per kilo per hour, or 12 per cent lower than a series conducted at the same time without amytal. The individual variation in metabolic rate was -5 per cent and +8.5 per cent from the average, or very slightly less than the variation in animals not receiving amytal. The dose of 7 or 8 mg. for an animal of about 450 gm. was sufficient to make it close its eyes and lower its head as if asleep, but not enough to make it lie down. It recovers from the effects of this dose very rapidly but not before the determination is completed.

PRECAUTIONS

1. The system *must* be absolutely air tight. It should be tested frequently, if not after each determination by putting a weight on top of the spirometer and observing the gas volume within the cylinder.

2. At first thought, motion of the animals would appear to be a serious source of error. With the exception of an occasional animal, which must be discarded, this error can be eliminated, even though a guinea pig cannot be trained as can dogs or some other animals. Usually, darkening the chamber while the test is being made is of great advantage. If this is done, the animal chamber must be balanced in such a way so that motion can be detected. By recording the rate of consumption every five minutes, however, any movement will be quickly detected by the increased oxygen consumption. The animals must be starved at least fourteen hours, before each determination, but if starved for more than eighteen, they are apt to be restless on account of hunger. Guinea pigs do not tolerate cold quarters. If a metabolic determination is made while the animal is cold, it will, as expected, be elevated 15 to 25 per cent. It is therefore essential that the temperature of their quarters as well as the room where the determinations are made, be kept as warm as 24° C. and that the animal chamber also be kept warm (preferably 25° to 28° C.) while tests are being made. The apparatus must be protected from draughts of air. Although one can correct for changes in temperature within the system, this change will lead to less error if it is reduced to a minimum.

3. When gas volumes are recorded, the spirometer must be adjusted so that the two water menisci are on the same plane, and the reading must be made a few seconds after Bottle *B* has emptied.

4. Before each determination, the spirometer must be emptied and filled with oxygen, not air. If air is used, the depletion of oxygen within the system may lead to an enormous error (decrease in consumption as measured by the spirometer).

SUMMARY

We have described a simple apparatus, easily and cheaply constructed, which in our hands has yielded constant and presumably accurate results in determining the metabolic rate in small animals. We have used it only on guinea pigs, but see no reason why it could not be used for rats, especially if the sizes of the various chambers were reduced. By using proper precautions and discarding an occasional animal, movement can be entirely eliminated as a serious source of error. No claims for originality in construction of the apparatus are made.

A COMPARISON OF THE WASSERMANN AND KAHN REACTIONS UPON SPINAL FLUID IN TREATED AND UNTREATED CASES OF PARESIS*

DE LESTER SACKETT, B.S., AND ERIC ESELIUS, B.S., ELGIN, ILL.

A LARGE number of articles have appeared in the literature comparing the results of the Wassermann and Kahn reactions since Kahn introduced his test in 1922.¹ The Kahn reaction has been compared with many Wassermann technics, and at the present time it is generally accepted that there is a very close agreement between the results of the two tests upon blood serum.

Although we cannot agree with those individuals who, for various reasons, recommend that the Kahn can completely replace the Wassermann reaction upon blood serum as a routine procedure, we do believe that the Wassermann tests should likewise not be run independently. It is our opinion that the greatest value of any precipitation reaction is that it serves as a necessary check to the complement fixation reactions. All complement fixation reactions should be controlled by a recognized precipitation test, and vice versa, and never by a technic based upon the same underlying principles.

The Kahn reaction upon spinal fluid is also of value in the serology of syphilis, but has not been accorded the enthusiastic approval received by the same test upon the blood serum. Although many articles have been published containing a series of parallel Wassermann and Kahn reactions, which show a close agreement between the two tests, articles have appeared indicating that negative Kahn tests are frequently found upon spinal fluids of incompletely treated cases of neurosyphilis. This is in direct contrast to that found in the results of the reaction upon blood serum, for in this case it has been repeatedly pointed out that the Kahn reaction appeared to be slightly more sensitive than the Wassermann.

LITERATURE

Kahn² reported the comparative findings of the Wassermann and Kahn tests upon 750 spinal fluids as follows: perfect agreement, 670 (394 positive, 276 negative) results stronger in Wassermann, 44, results stronger in Kahn, 26, and in 10 anticomplementary Wassermanns, satisfactory results were obtained with the Kahn.

Again Kahn³ reported the findings of his test and the Harrison Wassermann method as follows: Four-plus reactions in the Wassermann 177, Kahn 223; 63 two-plus Wassermanns and 18 one-plus Kahns. Neither reaction gave any false positive results. These findings would indicate that the Kahn test was superior to this Wassermann technic.

*From the State Psychopathic Institute.
Received for publication, March 16, 1933.

Lederer¹ compared the results of the two tests upon 57 spinal fluids and found that the tests agreed upon 33 negative and 19 positives. There was one relative agreement and in four treated cases the Wassermann was more or less positive while the Kahn was negative. Using a modified Kahn technic he compared the two reactions upon 73 spinal fluids with the following results: 39 negative with both tests and 17 positives in perfect agreement, one fluid giving a weakly positive Wassermann gave a negative Kahn, and in 7 fluids the Wassermann was negative and the Kahn more or less positive.

Rabinovitch and Roberts² reported a series of 112 spinal fluids in which there was perfect agreement in 101 (63 negatives and 38 positives), and divergent results in 11 (4 stronger in the Wassermann, 6 in the Kahn), and one positive Kahn upon a fluid which gave an anticomplementary Wassermann reaction. They also observed that there was not any relation between the strength of the Kahn test and the amount of globulin present in the fluid.

Davenport³ examined 487 spinal fluids with the Kahn tests and obtained negative reactions upon 5 cases of neurosyphilis in a group of 118 diagnosed cases. He also obtained negative reactions upon 23 incompletely treated cases. The results of the Kahn test upon the remaining fluids in his group were in agreement with the clinical findings.

Hull, Fry and Garwood⁴ in 180 syphilitic cases found 135 positive and 45 negative Kahn reactions upon the spinal fluid. All but 14 of the negative tests were from patients who had received antisyphilitic treatment. On 229 fluids from patients classified as nonsyphilitic, 7 positive Kahn tests were procured. Of these 7 positive tests, 2 four-plus and 1 three-plus reactions were confirmed by positive gold sol reactions. The remaining had weak gold curves and weaker Kahn reactions. These authors conclude that the Kahn tests upon spinal fluid have a high degree of specificity in eliminating the possibility of cerebrospinal syphilis.

Germat and Serafimov⁵ compared the Kahn and Wassermann reactions upon the fluids of 50 cases with clinical syphilis. They found complete agreement between the two tests in 94.5 per cent and divergence in 5.5 per cent. In the latter the Kahn gave more positive reactions. In progressive paralysis treated with malaria and sulphur in oil, the Kahn retained a stability of the positive reaction. Only one case with prominent improvement of the patient gave a negative Kahn test. They conclude that the Kahn reactions have a fairly simple technic and deserve great attention.

This brief review of the literature does not pretend to cover the subject, but is offered to demonstrate the diversified opinion as to the value of the two reactions.

TECHNIC

Because of the great dilution of the spinal fluid, it is first necessary to concentrate the reacting substances in the fluid by the precipitation of the globulin with ammonium sulphate and then testing the redissolved globulin by the Kahn reaction.¹ Since ammonium sulphate in sufficient concentration is capable of producing a precipitate with the antigen, more salt solution must

be used in the antigen dilution. This is usually between 0.3 to 0.4 c.c. more per 1 c.c. of antigen than the standard titer.

It is evident that this weakening of the antigen would more or less affect the strength of the reaction obtained with its use. Kurtz and Larkum⁹ following the suggestion of Kahn and McDermott¹⁰ have devised a technic which sufficiently removes the excess ammonium sulphate so that the regular serum titer can be used. After precipitating the globulin with the sulphate and centrifuging the specimen to throw down the precipitate, they pour off the supernatant fluid and invert the tube in saline, dipping it up and down, taking care that the saline does not touch the precipitate at the bottom of the tube. The air is allowed to escape by means of a glass tube reaching from the entrapped air in the tube through the saline into the open air of the room. This procedure is carried out in triplicate on each specimen and the globulin dissolved in 0.3, 0.2, and 0.1 c.c. saline. They found stronger reactions in those tubes containing the more concentrated globulin solutions.

We have been able to accomplish the removal of the excess ammonium sulphate by a technic which we feel to be simpler and to have less opportunity for mechanical accidents. In using the technic of Kurtz and Larkum unless great care is used in rinsing the tube in the saline solution, there is a possibility of losing some of the globulin because of splashing. Globulin is very soluble in saline, so, of course, any saline coming in contact with it would result in a loss of globulin and reacting substances.

MODIFICATION OF TECHNIC

Our method differs from the technic just outlined in that after the globulin has been thrown down by centrifuging, the supernatant fluid is carefully pipetted off, the tube is placed in an inverted position upon some filter paper and allowed to drain for one-half hour. Then the inner sides of the tube are carefully dried by means of a cotton applicator, taking great care not to disturb the precipitated globulin. The globulin is then ready to be redissolved and the regular Kahn technic continued, except that the antigen serum titer can be used. In our study we did not concentrate the globulin dilution, but followed the routine Kahn procedure for spinal fluid.

In removing the supernatant fluid it was found that if great care was used, it could be poured instead of pipetted off without affecting the end-result of the test.

EXPERIMENTAL STUDY

We have compared the results obtained upon 202 spinal fluids with the Wassermann (Craig technic¹¹), standard Kahn, and modified Kahn (employing the serum antigen titer) reactions. This group consisted of 64 cases of untreated paresis, 90 cases of treated paresis, and 48 cases that were not considered to be paretics. The therapy used in the treated cases consisted of various fever therapies (diathermy, electric blanket, malaria and sulphur in oil) and tryparsamide. The spinal fluids were examined at a period ranging from two weeks following treatment to two years.

Considering the group as a whole there was a perfect agreement between

the three tests in 119 cases or 58.91 per cent (72 positives and 47 negatives). It would be very difficult to determine the relative agreement between the three tests, as many fluids had a relative agreement with two of the reactions but an absolute disagreement with the third test.

Chart 1 plots the curve of the perfect agreement of the spinal fluid Was-

Chart 1.—Perfect agreement between spinal fluid Wassermann and Kahn reactions.

Chart 2.—Perfect or partial agreement between spinal fluid Wassermann and Kahn reactions.

sermann and the two Kahn reactions. There was 100 per cent agreement between the Wassermann and the standard Kahn in the 48 cases not diagnosed as paretics and having negative blood findings. In the 64 untreated cases of paresis, the agreement drops to 81.25 per cent or in 52 cases. In the treated cases this drops still further, or in only 20 of the 90 cases, or 22.2 per cent. There was one false two-plus reaction by the modified Kahn test among

the 48 nonparetics, thus making a 97.91 per cent agreement between this and the Wassermann reaction. In the untreated cases there were 60 cases in which there was a perfect agreement between the two tests or 93.75 per cent. This percentage dropped to 60 per cent or a perfect agreement in only 51 of the treated cases.

Chart 2 considers the sum of the perfect and relative agreement between the tests. The Wassermann and the Standard Kahn reactions had 100 per cent agreement in the nonparetics; in the untreated cases, 62 cases or 96.87 per cent had either a perfect or partial agreement, and in the treated cases this dropped to 52.2 per cent or 47 cases.

The Wassermann and modified Kahn reaction had a perfect or relative agreement in 47 of the nonparetic or 97.91 per cent, in the untreated cases

Chart 3.—Positive reactions in spinal fluid.

there was 100 per cent perfect or relative agreement and in the treated cases this agreement held true in 77 cases or 85.5 per cent.

Chart 3 plots the positive reactions of the three tests. There were no positive Wassermans in the fluids of the nonparetics, 100 per cent of the untreated cases of paresis had positive spinal fluid Wassermans and 86 cases or 95.5 per cent of the treated cases also had positive reactions with this test.

The standard Kahn reaction gave no positive reactions in the nonparetics; in the untreated cases, 62 or 96.87 per cent and in the treated cases, 44 or 48.8 per cent had positive reactions.

The modified Kahn test gave one false positive reaction in the nonparetic cases or 2.08 per cent, 100 per cent positive reactions in the untreated cases and in the treated cases 70 or 77.7 per cent had positive reactions.

Chart 4 demonstrates the comparative strength of the three reactions. The Wassermann and the standard Kahn both had all negative reactions in the nonparetics, but in the untreated cases the Wassermann was stronger than

the standard Kahn in 8 cases or 12.5 per cent. The standard Kahn was not stronger than the Wassermann in any of the untreated cases. In the treated cases the Wassermann exceeded the strength of the standard Kahn in 70 cases or 77.7 per cent, while the Kahn was stronger than the Wassermann in one case or 1.1 per cent.

Comparing the Wassermann and the modified Kahn reactions, we find that the modified Kahn had one false positive reaction in the nonparetics so that 2.08 per cent of those cases had stronger precipitation reactions than complement fixation. In the untreated cases there was a perfect agreement between the two tests, while in the treated cases the Wassermann was the stronger in 28 cases or 31.1 per cent. The modified Kahn was stronger than the Wassermann in only 6 cases or 6.6 per cent of the same group.

Chart 4.—Comparative strength of the spinal fluid Wassermann and Kahn reactions.

DISCUSSION

It will be noticed from the preceding data that our findings are in great disagreement with other authors. We feel this is due to the great number of treated cases included in our survey, because if only the nonparetic and untreated parietic cases are considered, there would be a relatively high percentage of agreement between the reactions. (Perfect agreement between Wassermann and standard Kahn, 89.2 per cent; Wassermann and modified Kahn, 95.5 per cent.)

Unfortunately the amount of fluid submitted for examinations was not great enough for us to follow completely the suggestion of Kurtz and Larkum and concentrate the globulin to a further extent than that of the standard Kahn technic. Undoubtedly, we would have found as they did, that more positive and stronger reactions could be obtained. However, in view of the fact that

we found one false positive among the 48 cases of nonparetics with the modified Kahn procedure, it would suggest that upon further concentration of the globulin, these false reactions would be found in even greater numbers. We feel that this method would be a dangerous procedure unless carefully controlled by a recognized Wassermann test and clinical evidence.

It is worthy of note that our findings indicate a false impression is prevalent if the Kahn reaction alone is used in determining the success of the treatment of neural syphilis: so many of these fluids had negative Kahns, although the Wassermann reactions remained positive. We definitely recommend the latter as the more delicate and reliable test upon spinal fluids.

CONCLUSIONS

1. The Wassermann reaction (Craig) upon spinal fluid gives a higher percentage of positive reactions in treated and untreated cases of paresis than the standard Kahn or the modified Kahn employing the serum antigen titer.

2. A new method is given to remove the excess ammonium sulphate from the precipitated globulin, which we feel is as efficient and more simple than the method of Kurtz and Larkum.

3. The agreement between the three reactions is relatively high in nonparetics and untreated paretics, but falls off rather sharply in treated cases.

4. The modified Kahn reaction employing the serum antigen titer gave a higher percentage of positive reactions in treated and untreated cases of paresis than the standard Kahn test.

5. One false positive reaction was observed among 48 nonparetics with the modified Kahn reaction, indicating a possibility of error if this test is used exclusively.

We wish to take this opportunity to thank Dr. Sidney D. Wilgus, Director of the State Psychopathic Institute, for his interest, helpful guidance and suggestions in the preparation of this study.

SPECIAL RACK FOR SMITH FERMENTATION TUBES AND "U" TUBES*

PAULINE EPSTEIN, NEW YORK, N. Y.

ONE of the means of identification and differentiation of various strains of bacteria is the sugar reaction test, for which a Smith fermentation tube is used. The latter is filled with sugar broth into which the organism to be tested is inoculated. The amount of gas produced by the organism as measured by its volume in the arm of the tube, as well as the production of acid, as

Fig. 1.

evidenced by the change in the color of the sugar broth, frequently facilitates the classification of different microorganisms. However, due to its specific and cumbersome form, the wide use of the Smith tube has been found difficult.

In the process of the fermentation test the tube is subjected to numerous manipulations:

- A. Sterilization of the tube itself in hot air sterilizer.
- B. Filling it with culture media and sterilization of the media in the autoclave or Arnold.
- C. Inoculation with the organism to be tested and incubation for its growth, etc.

In the course of this handling the tube, because of its thin stem, too often breaks. In addition, due to its instability, the tube frequently tilts or falls and displacing part of the gas in the arm by the broth, disturbs the test. To avoid the breakage and to secure the results of the test, I devised a rack which

*From the Department of Bacteriology, New York University and Bellevue Hospital Medical College.

Received for publication, April 10, 1933.

has been successfully used for some time in our laboratories. This rack consists of a base and a vertical plate. The base, 13.5 inches by 7.5 inches, is made of a metal frame and a wire mesh, which has 16 openings per square inch, thus allowing free circulation of steam or heated air during sterilization.

The vertical plate, 7.5 inches by 13.5 inches is centered at the base. Attached to the plate, centrally located, are six clasps at $2\frac{1}{4}$ inches spacing on each side.

Directly above and below each clasp there is a $\frac{3}{4}$ inch diameter opening punched through the plate. The sides of the clasps also have $\frac{1}{4}$ inch diameter

openings. The holes in the plate as well as those in the clasps enhance further circulation of air and the maintenance of a uniform temperature through the entire surface of the rack.

The rack is designed to hold "U" tubes as well as Smith fermentation tubes. In either case, the long arm of the tube is placed in the clasp, while in the Smith fermentation tube the stand rests on the base of the rack, thus affording a double support, as shown on the end view of the rack.

Monel metal was used in the construction of the rack because it is rust-proof and preserves its appearance. It is a solid unplated metal, white, very hard and can therefore be subjected to various temperatures.

DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

DERMATITIS, Contact, Patch Test in the Diagnosis of, Ayres, S. Jr., and Anderson, N. P. *Ann. Med.* 6: 1161, 1933.

The advantages of the patch test in determining the etiology of certain cases of dermatitis are mentioned, together with a description of the method of applying the test.

Twenty-four cases of eczematoid dermatitis are reported, some of them in detail, in which the etiology was established by means of the patch test.

The method advocated by the authors is as follows:

If the substance is a chemical it should be applied in approximately the same dilution to which the patient has been previously exposed. Leaves of plants and shrubs should be as fresh as possible. Dry powders may be moistened slightly with water. The substance to be tested is placed on a small square of cotton about the size of a postage stamp which is then applied to the flexor surface of the forearm, or other suitable area, and covered with a square of some impervious material such as cellophane, which should be about four times as large as the test area. This external covering is then held firmly in place by wide strips of adhesive tape. The space on all sides between the edges of the central cotton square and the edges of the cellophane is sufficient to prevent the adhesive tape from coming too close to the test area. Otherwise the mild temporary irritation which usually results from the adhesive tape might interfere with an accurate interpretation of the reaction. The patch test is allowed to remain undisturbed for twenty-four hours unless discomfort from irritation justifies its removal before this time. A positive reaction is characterized by a sharply defined square of redness corresponding in size and shape to the central test area. Papules and vesicles are also usually present, corresponding to the appearance of the original eruption. Evidences of the reaction can usually be noted for three or four days or longer after the test is applied. In rare instances the reaction may not develop for forty-eight hours after the test is applied.

The test is simple, inexpensive, and closely simulates the natural conditions under which the dermatitis developed. It is usually very accurate. A few cases have been reported in which only certain areas of the skin were hypersensitive so that in the case of a dermatitis of the face, a patch test on the arm was negative while one performed on the face after the eruption had subsided was strongly positive. Such instances are probably uncommon, but the possibility should be borne in mind.

BLOOD PROTEINS, A Micromethod for the Quantitative Estimation of, Medes, G. *Am. J. Clin. Path.* 3: 439, 1933.

One and five-tenths cubic centimeters of blood from the ear of a rabbit is allowed to drip directly into a centrifuge tube containing powdered potassium oxalate, with which it is thoroughly mixed. The tube is centrifuged at 3,500 revolutions a minute for four minutes. The plasma is syphoned off through a fine glass syphon into a small straight-sided vial containing a 2-holed rubber stopper through one hole of which passes the syphon, and through the other, a short glass tube connected by rubber tubing to a glass mouthpiece. By this arrangement the stream of plasma through the syphon can be regulated and the plasma removed from the mass of cells to almost the last drop. The plasma is then distributed to previously prepared 10 c.c. volumetric flasks by means of a Folin tube for micro determination of blood sugar, accurately graduated in 0.1 and 0.2 c.c. graduations.

Preparation of Flasks: The following amounts of anhydrous Na_2SO_4 are weighed on an analytical balance into a series of 10 c.c. flasks: (1) none, (2) 1.07 gm., (3) 1.42 gm., (4) 1.78 gm., (5) 2.204 gm. Into Nos. 2, 3, 4, and 5 are added 0.4 c.c. of a buffer solution to be described below. To all five tubes is added water at 35° to just below the 10 c.c. mark.

The flasks are stored in an incubator at 35° in order to maintain the Na_2SO_4 above its eutectic point. When ready for use, 0.1 c.c. plasma is measured into each of Nos. 1, 2 and 3, and 0.2 c.c., into Nos. 4 and 5, the volumes made up to 10 c.c. with warm water and the flasks returned to the incubator for three hours.

Composition of Buffer (Berglund): 29.6 c.c. of 0.2 M carbonate free NaOH, 50 c.c. 0.2 M of KH_2PO_4 , distilled water (carbonate free) to make 100 c.c. This should give a solution with pH 7.0

At the close of the three-hour period, the contents of Flasks 2, 3, 4, and 5 are filtered. A fine smooth filter paper 6 cm. in diameter is employed. The filtrates are collected in graduated centrifuge tubes; 9 c.c. can usually be procured. At the same time 9 c.c. of the contents of Flask 1 are transferred to centrifuge Tube 1. To each of the five tubes is added 1 c.c. of 50 per cent trichloroacetic acid and the contents thoroughly mixed by means of a fine glass rod which is then washed off with 4 per cent trichloroacetic acid. The centrifuge tubes are allowed to stand for ten minutes at room temperature, and are immersed for ten minutes in a water-bath at 50° C. They are centrifuged at 3,500 revolutions per minute for twenty minutes, after which the supernatant fluid is decanted and the precipitate dissolved in one or two drops of 10 per cent NaOH stirring thoroughly with a fine glass rod and spreading the NaOH over the entire inner surface of the centrifuge tube. The contents are then made up accurately to the original volume (9 c.c.).

The nitrogen of each of these solutions is determined by Folin's micro Kjeldahl method, employing 2 c.c. of each. Occasionally 3 c.c. may be required for some of the lower fractions of globulin.

Computation:

$$S \times \frac{20}{R} \times \frac{10}{X} \times \frac{100}{Y} = N$$

where S = value of standard, R = reading of colorimeter, X = 0.1 or 0.2 c.c., according to the fraction being ashed, Y = No. of c.c. ashed, and N = milligrams protein nitrogen in 100 c.c. of plasma. To obtain the grams of protein per 100 c.c. of plasma, multiply by 6.25 and divide by 1,000. Total protein equals protein in Tube 1; fibrinogen equals Tube 1 minus Tube 2; euglobulin equals Tube 2 minus Tube 3; pseudoglobulin I equals Tube 3 minus Tube 4; pseudoglobulin II equals Tube 4 minus Tube 5; albumin equals Tube 5. In case values of only total protein, fibrinogen, globulin and albumin are desired Tubes 3 and 4 are omitted.

MALARIA, A Method of Making Slide Smears From Female Anopheles, etc., Barraud, P. J. Ind. J. Med. Res. 21: 457, 1933.

The advantages of the technic described may be summarized as follows:

1. The method combines, in the large majority of preparations, the advantages of dissection of the salivary glands, with those of Sergeants' method for detecting the presence of sporozoites in the body-fluid of mosquitoes.

2. The insect host is preserved for identification and for reference in the future.

3. The method can be carried out rapidly in the field where laboratory facilities, and sufficient time, for carrying out dissections in the ordinary way, are not available.

4. The preparations can be made by an assistant not necessarily trained in the detection of sporozoites, or in the identification of mosquitoes.

5. A microscope is not necessary for making the preparations.

The apparatus required is as follows: A supply of test tubes with wool plugs; a supply of microscopical slides; two needles, or pins (preferably mounted in handles); some staged tubes; a supply of small double-pointed entomologic pins and a pair of entomologic forceps. A chloroform tube, or a supply of chloroform, is also useful. The slides may be prepared previously by marking off three spaces by drawing transverse lines with a diamond, about one inch apart, and numbering these consecutively.

The mosquitoes are caught in test tubes. When a preparation is to be made, kill the

insect with chloroform, or by blowing tobacco smoke into the tube. When dead, turn the specimen out on to a slide. Arrange the whole mosquito on a numbered square, on its left side, with the head pointing away from you. Do not add any saline, or other fluid, as this is not required. Do not remove the wings or legs, and endeavor to carry out the following manipulations with as little damage as possible to the scaling, etc. Take a needle in the left hand and place the shaft of this flat across the front of the thorax. Press down with this so as to cause the thin chitin of the front of the thorax below the neck ("prosternum") to bulge out considerably.

The salivary glands lie just within this thin sheet of chitin. With a needle held in the right hand cut into this part. Draw out, and cut off, the tissues which will protrude, and by continued pressure with the left hand needle at the same time, squeeze out some of the body fluid on to the slide. Endeavor to avoid severing the neck, or detaching the front legs. Tip the mosquito on to a piece of paper, and with a needle rapidly mash up and make a small circular smear, on the numbered square, of the tissues and fluid left on the slide. Dry this by waving the slide in the air. It should be noted that the dissection and smear are made without any admixture of saline. When opportunity occurs the smear should be fixed with methyl alcohol or absolute alcohol, and the slides stored for staining and examination, which may be done at any convenient time later.

Pin the mosquito and mount it in a staged tube, marking on the stage the number corresponding to the smear on the slide. Observations on the locality, the nature of the place where the specimen was collected, the date, and any other details considered worth recording, should be entered in a notebook at the time.

Before making another preparation clean the needles thoroughly.

GNOCOCCI, Cultivation of, Philadelphia, A. *Wien. Klin. Wchnschr.* 46: 1052, 1933.

Two parts sterile human or horse blood are mixed with one part of distilled water in a flask. The flask is closed with a sterile glass stopper and shaken vigorously for three minutes to prevent coagulation. It is then kept in the incubator at 60° for half an hour. After this time a foamy mass of fibrin collects at the top, while the dark red blood serum is fluid. This is mixed in a proportion of 1 to 2 with nutritive agar at 60° with a 2 per cent agar content and a P_H of 7.3 to 7.5. The nutritive medium is ruby red and transparent.

The author made 415 cultures from 108 patients suspected of gonorrhea. In 354 instances the cultures agreed with the microscopic findings. In 29 instances the cultures showed growth of gonococci though no gram negative gonococci were found microscopically. In four cases that were doubtful microscopically cultures gave positive results. In three cases that were positive microscopically there was no growth of the cultures. The results of cultivation on blood serum agar were at least as good as those on ascites agar.

IODINE, An Improved Micromethod for Estimating, Patnaik, M. *Ind. J. Med. Res.* 21: 237, 1933.

The sample for analysis is rendered alkaline. Fats and oils should first be saponified with 10 per cent alcoholic potash, then evaporated to dryness in a porcelain basin and dissolved in hot water. Cereals and vegetables should be heated with alkali till a complete paste is obtained. Whatever the sample may be it should be converted into an easily workable form. To such an alkaline solution 7 per cent solution of $KMnO_4$ is gradually added and while stirring with a glass rod the porcelain basin is heated over an asbestos protected flame. When the oxidation is complete and there is a slight excess of $KMnO_4$, absolute alcohol is added slowly until the excess of $KMnO_4$ is reduced. It is then cooled and filtered quantitatively and the hydrated manganese dioxide removed. The filtrate is then evaporated to dryness with a small amount of K_2CO_3 . The residue which always contains some nonoxidizable disintegration product, besides potassium iodate, is heated over a protected flame till charring takes place without the evolution of smoke (some amount of smoke is evolved from fats and oils at this stage—the amount of smoke being very much less than that in the usual incineration method). It is then heated slowly over a mild flame till the organic matter is

disorganized. During this process of heating, all the iodate coming in contact with the finely divided carbon is reduced to iodide. It is then made into a paste and extracted and estimated as usual.

If during incineration the charred mass remains in a molten state due to an excess of potash, a requisite amount of K_2CO_3 should be added to render the final product suitable for alcoholic extraction.

For the determination of iodine from pure $KMnO_4$, 50 gm. of $KMnO_4$ is taken, and after reduction with alcohol it is filtered quantitatively. The filtrate is evaporated in five nickel dishes after addition of 3 gm. of K_2CO_3 to each dish. Then before the evaporation is complete one gram of sugar (there being no iodine in sugar) is distributed among the five dishes. The rest of the process remains the same. In every determination the amount of iodine present in the $KMnO_4$ used up is subtracted in order to get the actual value.

SYPHILIS, Flocculation Tests For, Mudge, E. Am. J. Clin. Path. 3: 421, 1933.

The following tests were compared in 1,000 blood specimens: Flocculation tests: Eagle, Hinton, Kahn, Kline, Meinicke (M.K.R.), and Miller (M.B.R.). Complement fixation tests: Kolmer quantitative, and a double antigen test.

This series has shown the advantage of performing a complement fixation test and a flocculation test on every blood specimen as supplemental to each other.

The flocculation tests have a definitely higher degree of sensitivity than the complement fixation tests in treated and latent cases of syphilis.

The majority of the tests concerned have a high degree of specificity.

All eight tests require a high degree of technical skill, and increasing experience with any test enhances its value.

SERUM PROTEINS, Diagnostic Value of Changes in Kala Azar, Mudaliyar, M. R. G., Sundarum, S. K., and Ramachandran, A. S. Ind. J. Med. Res. 21: 361, 1933.

The serum protein changes in kala-azar while not absolutely diagnostic of the disease offer distinct help in diagnosis of kala-azar in doubtful conditions.

The essential changes in serum proteins in kala-azar are a fall in albumin with considerable rise in total globulin, associated with increase in the relative proportion of euglobulin. A similar, but less striking change, has previously been recorded by Lloyd in secondary syphilis.

Serum protein changes in a number of miscellaneous conditions have been recorded.

B. PERTUSSIS, Rapid Agglutination Technic Applied to, Kendrick, P. L. Am. J. Pub. Health 23: 1310, 1933.

Antigen.—The forty-eight-hour growth of *B. pertussis* on a Bordet-Gengou slant is transplanted to a half Petri plate of Bordet-Gengou medium. After forty-eight hours' incubation, the growth is removed with a stiff, bent needle and emulsified in 1.5 c.c. of physiologic salt solution. The suspension is filtered and adjusted, if necessary, to a turbidity of approximately 10 billion organisms per c.c. by comparison with a standard.

Filtration is an important step in obtaining satisfactory smooth suspensions. Test tube filters are prepared for this purpose. A thin layer of moistened cotton is shaped around the finger, placed on a simple copper wire netting support, and inserted in a $5 \times \frac{5}{8}$ tube, the free end of the wire strip being bent to hook over the lip of the tube. The cotton is molded against the walls of the tube by means of a wooden applicator. These filter tubes are plugged with cotton and sterilized. The filter is easily removed after use and the plug reinserted.

For a larger filter, a layer of gauze and cotton is wrapped around the outside of a square of wire netting cut from a bias strip and shaped to fit inside the neck of the bottle or flask of the desired size. The filter is suspended by two wires which cross under it, pass through the netting, and are hooked over the lip of the flask.

Antiscrum.—For preparation of a diagnostic serum, a rabbit is injected intravenously with a 10 billion per c.c. suspension prepared from a forty-eight-hour growth of a recently isolated *B. pertussis* culture to which merthiolate 1:10,000 has been added at least twenty-four hours previously. The injection doses are 0.4 c.c., 0.8 c.c., and 1.0 c.c., respectively, at three- to four-day intervals. About 1 week after the last injection, the agglutination titer (equivalent, as explained below) has been around 1:20,000 in the six different rabbits treated by this method. The serum dilutions for agglutination tests are chosen according to the particular conditions. For testing cultures isolated by the cough plate method, the dilutions usually employed are 1:10, 1:100, 1:500, 1:750, 1:1,000, 1:1,500, and 1:2,000. For uniformity, the same dilution scheme is always employed and separate pipettes are used for the different dilutions.

The agglutination test—one-tenth c.c. of each serum dilution is mixed with 0.1 c.c. of antigen, the measurements being made with 1 c.c. pipettes graduated in tenths. For an antigen control, 0.1 c.c. of saline is mixed with 0.1 c.c. of antigen. The mixtures are shaken by hand for three minutes. For the shaking process, the racks are rocked at the rate of approximately 60 back-and-forth motions per minute and in such a way that the contents flow up the walls of the tubes for about three-quarters of their length. After the shaking period, physiologic salt solution is added for greater ease in reading. Because of its convenience, the Hipple pipetting apparatus, used in the Kahn test and set to deliver 0.5 c.c. of saline, is ordinarily employed.

Reading the tests—the tests are read immediately after the addition of saline and each tube recorded as —, ±, +, ++, +++, or +++++, according to the degree of agglutination. In the interpretation of the results in comparison with those given by other workers, a question arises because the final dilutions in the rapid test are not strictly comparable with those ordinarily given. This is of small consequence, however, provided the method of expressing the results is clearly stated. In the 0.2 c.c. mixtures of the rapid test, the series of serum dilutions 1:10 to 1:2,000 would give a series of final dilutions from 1:20 to 1:4,000. Any particular final dilution in the usual 1 c.c. test would contain five times the actual quantity of serum and antigen contained in the same dilution of the 0.2 c.c. rapid test. Therefore, if based on the actual quantity of serum present in the mixture, the series of final dilutions 1:20 to 1:4,000 of the rapid test would be equivalent to a series 1:100 to 1:20,000 in the usual 1 c.c. test.

TYPHOID BACILLI, Isolation of From Water and Sewage, Wilson, W. J. Brit. M. J. 3794 (Sept. 23), 560, 1933.

The method following is described as very efficacious:

To 100 c.c. of 3 per cent nutrient agar were added 10 c.c. of a stock glucose-phosphate-sulphite-bismuth mixture, and 1 c.c. of a 1 per cent solution of brilliant green. Equal volumes (25 c.c.) of the medium, cooled to 55° C., and water were mixed and poured into Petri dishes. After the medium had set and been incubated, black colonies consisting of typhoid bacilli developed in its substance. These were subcultured on to MacConkey plates, and cultural and serologic tests applied.

The bismuth media are very easily prepared when a stock solution is available, and such stock solutions keep for months. Dissolve 6 grams bismuth-ammonio-citrate scales in 50 c.c. of boiling distilled water, and neutralize by the addition of about 2 c.c. of 10 per cent caustic soda. Mix with a solution obtained by boiling 20 gm. sodium sulphite anhydrous in 100 c.c. of water, and then, while the mixture is boiling, add 10 gm. of sodium phosphate anhydrous. To the sulphite-bismuth-phosphate mixture, when cool, add a solution of glucose obtained by dissolving 10 gm. of commercial glucose in 50 c.c. of boiling distilled water. For preparation of old standard medium, add to 100 c.c. of a hot melted 3 per cent nutrient agar 20 c.c. of stock mixture, then 1 c.c. of an 8 per cent solution of ferrous sulphate crystals in water, and 0.5 c.c. of a 1 per cent solution of brilliant green in distilled water; pour into Petri dishes, and when the medium has set inoculate the surface. Isolated colonies of *B. typhosus* and *B. para-typhosus* are black, the typhoid colonies usually appearing within twenty-four hours, and the paratyphoid within forty-eight hours.

UNCINARIASIS, Acute From Massive Infestation and Its Implications, Ashford, B. K., Payne, G. C., and Payne, F. K. J. A. M. A. 101: 843, 1933.

In the discussion of an outbreak following prolonged bathing in polluted water the authors comment that the secret of what happened to these patients is found in a study of the leucocytes.

First, infestation, when sufficiently massive, produces leucocytosis, and this leucocytosis is eosinophilic. In every one of these cases this occurred and on these abnormalities, with a history of ground-itch, sudden loss of strength and color, and, generally, diarrhea, the correct diagnosis should be strongly suspected, if not actually made clinically, as in this instance it was made. In these cases, in from one to two months after infestation, a high leucocytosis was found already developed. It oscillated for two or three months and then, throughout nine months, gradually sank to near or quite normal.

But if the leucocyte count is striking, the eosinophile percentage is still more so. When the patients were first examined, this percentage was found to lie all the way between 14 and 69. When most of the worms in the intestine had been expelled, the percentage arose; but this was not on account of the expulsion of the worms. There is, we believe, a more reasonable explanation: There is a growing feeling that eosinophilia is a phenomenon related to the disintegration and absorption of foreign protein. The old idea that eosinophilia in uncinariasis is due to a toxin produced by the worm can no longer be accepted in its literal sense. The eosinophilia rises when the larval mortality in the tissues rises.

BIOPSY, Present Status of, McGraw, A. B., and Hartman, F. W. J. A. M. A. 101: 1205, 1933.

The worth of the biopsy in diagnosis, prognosis and as an index for treatment is at present thoroughly and soundly established.

Properly conducted, its lack of danger is likewise established. Its few contraindications are well known and recorded.

Its status as a technical procedure, though clearly allowing of future improvement, has attained a satisfactory level of combined simplicity in procedure and materials and of reliability in preparation.

Its opportunities for future development and practice under optimum conditions lie largely in stimulation of interest and furnishing of facilities for more pathologists and surgeons to devote the time and hard work necessary to perfect themselves in the difficult field of tumor pathology.

POLYCYTHEMIA, Benign Familial, Spodaro, A., and Forkner, C. E. Arch Int. Med. 52: 593, 1933.

Observations on the blood, together with other clinical studies, of ten members (two generations) of a family in which polycythemia and splenomegaly were present are reported. The existence of polycythemia in an earlier generation of the family is suggested by the history.

This family differed from those previously described in that characteristics of polycythemia vera, other than the increased number of red blood corpuscles and enlargement of the spleen, were not present.

The term "benign familial polycythemia" is suggested to distinguish this condition from polycythemia vera and from polycythemia due to recognized causes.

Some Pitfalls in the Study of Sex Hormones

ONE of the most diligently cultivated fields of scientific investigation at the present time is that of the interrelations between the gonads and the anterior hypophysis, the fruits of which have already amassed a large volume. As is always the case, much of this literature is confusing in its conclusions, with, oftentimes, a blind following of methods already outmoded. In the following paragraphs an attempt will be made to evaluate some of this literature in terms of actual accomplishments, with a view of aiding further work along this line. The whole subject has been amply reviewed by many able investigators and a duplication of this will not be attempted, the aim being rather to correlate certain phases of the work.

As one examines the literature it is evident that the same criteria of the efficacy of administration of the sex hormones is fairly general, the weights of the gonads of immature animals which have received injections for a short period, usually two or three days, with the opening or closure of the vagina. In very

many cases, particularly with routine assaying of extracts, the latter test only is used, many investigators using the same animals repeatedly, with short intervals between each test.

It has been shown (Lipschütz, 1932; Swezy, 1933a; Evans et al., 1933; Fluhmann, 1933) that the ovary has no necessary relation to the vagina when hormones are administered experimentally, cornified cells occurring with the ovary in all stages of change between normal and excessive luteinization, and with or without large follicles, hence this test gives evidences only of the presence of the single factor responsible for vaginal changes. Lipschütz further showed that these vaginal changes may take place with no corresponding changes in either uterus or ovary. Much evidence is also accumulating to show that this factor is not identical with folliculin, progesterin, the growth, follicular growth, or luteinizing hormones, and is widely distributed, occurring even in plants. As was first demonstrated by Stockard and Papanicolaou (1917), the different stages of the normal estrous cycle of many of the lower mammals are characterized by clear-cut changes in the cellular contents of the vagina. Much experimental work has also shown that these changes are directly due to the action of hormones. The work shows equally well, however, that decreasing or increasing these hormones completely upsets the normal relations between them, resulting in conditions which diverge widely from the normal, not only in the ovary, but in the uterus, vagina, and even in the hypophysis itself. Under such conditions it is too much to expect that the vagina will still reflect the changes in the ovary. That this is true is abundantly proved by the results of much published work, in which all conditions of the ovary are associated with estrous smears as well as with diestrous ones. This fact that it does not give reliable information concerning the state of the ovary and uterus makes the vaginal smear method an unsuitable one for sole reliance as an assay test for sex hormones. In his recent review of the biologic assay of the sex hormone of the ovary, Marrian (1933) omits all mention of any other test for this hormone. That it is the sole test in so much of the work with hormones may well account for much of the variable results reported.

The practice of using the same animals repeatedly after a few days' interval has an even greater fault. The recent work of Emery (1933) shows that the ovaries of rats receiving injections of two castrated rat hypophyses on two successive days, reach a maximum size at twelve days and remain larger than the controls for about two months, when rats twenty-five days old are used. Since this is the usual age and length of treatment for experimental rats, it is evident that they will not be in optimum condition for some time after the initial treatment, as it is doubtful if results exactly comparable to those obtained in animals with ovaries in the normal immature state will be obtained in animals with ovaries already extensively luteinized. Even when no vaginal changes are found in these animals, it has been shown that changes in both ovary and uterus may take place (Evans et al., 1933), which might render their use a few days later of questionable value. The results reported by Selye and Collip (1933) show that early luteinization (day sixteen) will prevent the usual reaction of the ovary at a later date (day twenty-six) with continued injections. The work of Evans indicates the same possibility. The use of such animals may account for

much of the variable results obtained from different samples of these hormones put out by commercial laboratories, but the practice is by no means confined to such laboratories, as it is usually recommended for all routine work. Coward and Burn (1927) used animals not more frequently than once a fortnight, while Allen et al. (1930) used rats once a week. Coward and Burn found that out of 50 rats used three times, only 19 gave the same result each time. These were ovariectomized. Since these hormones affect the ovary mainly, it is probable that the differences would have been greater in normal animals. It is doubtful whether the disadvantages of using animals repeatedly, without a sufficient time elapsing for full recovery, can be compensated for by using large numbers of animals. This might be of little importance with many experiments, but for careful analytical work it is the attention to such small details which assures success.

The use of the weight of the ovary as an assay test is also open to criticism, since this is no infallible guide to the kind of change induced by hormone treatment, though excessive weights are nearly always associated with extensive luteinization. In a recent article Van Dyke and Wallen-Lawrence (1933) attempt to determine the differentiation of the follicular growth and luteinizing hormones by the weights of the ovaries induced in immature rats, without reference to the possible presence or absence of lutein cells in them. It is necessary that some follicular growth take place before a noticeable change in the weight of the ovary is obtained. But, since the luteinizing hormone may induce the formation of lutein cells from the germinal epithelium and tunica albuginea (Swezy, 1933a), it seems certain that evidences of the presence of this hormone may be found with but little change in either size or weight of the ovary. Selye et al. (1933) induced luteinization in the thecal cells of the small follicles of the ovary of the rat, beginning about day thirteen, with no macroscopic change in the ovary, with pregnancy extracts, and in the guinea pig without accompanying follicular growth. Any attempt therefore to determine the presence or absence of the luteinizing hormone in any preparation would involve a careful examination of stained sections of the ovary, even though no response had been elicited by the treatments in the vagina or in the weight of the ovary. In fact this seems more necessary in the case of the latter animals, as a pure luteinizing hormone would thus be demonstrated.

A considerable amount of follicular growth may also be found without a significant increase in the weight of the ovary. The presence of follicular growth hormone in small amounts could be detected only by the same means as has been suggested for the luteinizing hormone. Between this stage and that of extensive luteinization or the production of large follicles in great numbers, however, it is not always possible to determine from macroscopic examination what structures are predominant.

The relation of estrin, or factor inducing cornification in the vagina of rodents, to folliculin, or factor inducing growth in the endometrium, is one fraught with much confusion. In the normal animal these two factors seem to occur at approximately the same time in most cases, though this does not always hold true in the cat (Evans and Swezy, 1931). Under experimental conditions the preponderance of evidence indicates that the factor inducing cornifi-

cation is not identical with that inducing growth in the uterus, though the idea that they are one and the same seems to be prevalent. This acceptance of their identity has resulted in the widespread use of the vaginal smear test as the important one in the assay of these hormones.

Many investigators believe that a single hormone may be responsible for the changes in uterus and vagina, the relation being a quantitative one, yet, *in the normal animal, maximal growth of the endometrium is associated with cornification, this never occurring during the initial stages of growth when a smaller amount of hormone is presumably present.* Further evidence against this assumption is found in the work of Evans et al. (1933), in which all stages of growth of the uterus from medium to an estrous type and ovaries with medium and large follicles are present in rats treated with hypophyseal hormones and the vagina still closed. On the other hand, Lipschütz obtained vaginal changes with the administration of hypophyseal extracts but no changes in either ovary or uterus. The presence of cornification with no medium or large follicles, has been noted by a number of investigators, as well as ovaries filled with large follicles and a diestrous smear in the vagina. With these results in both normal and experimental animals, there seems to be no grounds for assuming that a single factor is involved in the changes in the vagina and uterus. Two separate factors are indicated.

Allen et al. (1930) found that the amount of estrin present in human corpora was highest after recent ovulations, days thirteen to sixteen, and lowest in ovaries with older corpora, in two cases at days twenty and twenty-two, and that there was an abrupt drop with menstruation. It is well known that in the first half of the ovarian cycle following ovulation, there are no large follicles in the ovary, these reaching a large size only toward the end of the cycle. Since ovulation seems to occur in the middle third of the cycle in the majority of cases, these relations would mean that the eight to ten days preceding menstruation would find only small to medium-sized follicles in the ovary. Frank and Goldberger (1926) find, however, that estrin reaches its greatest concentration near the first day of menstruation, the early part of the cycle showing only a small amount, with an increase from day ten to fifteen. If these were not cases in which ovulation occurred near menstruation, these results would suggest that the greatest concentration of follicular secretions came at a time when there were apt to be only small to medium-sized follicles in the ovary. This assumption is contradictory of much work on the lower mammals, since here the greatest concentration, as shown by the only critical test, the growth of the uterus, comes immediately preceding or coincident with ovulation. At first sight this would seem to mean that these physiologic processes and hormones differ radically in the human from those of the lower mammals, yet a considerable body of work indicates that they are very similar. Frank and his coworkers used only the presence of cornification in the vagina as the test of these hormones.

Cornification has no recognized place in the human cycle, hence the factor for it, found in a wide range of preparations, including plants, would seem to have no invariable relation to the ovarian cycle, while the factor causing growth in the endometrium does have a constant and invariable relation. The regularity of the uterine cycle in the human being, with its dependence on folliculin, is as

constant as may be found in the rat or guinea pig. There are no evidences yet brought out indicating a different hormonal relation. A clarification of these relations and the hormones associated with them can be obtained only by more critical analyses of the experiments conducted with them. In the light of present data it would seem expedient to restrict the use of the term estrin to the factor related directly to the vaginal changes, and, what is more important, to restrict the vaginal smear test to the assay of estrin, and not use it as a valid test for other hormones.

It has been pointed out elsewhere (Swezy, 1933b) that in all experimental work on normal animals, the hypophysis of the test animal itself largely decides the results when sex hormones are being studied. Whether this is true of other hormones also must be determined by further work. This result seems to be due to the presence of an activator in some preparations, including human pregnancy extracts and the hypophysis of the infantile rat, which is able to stimulate the hypophysis of the host to increased hormone production. This conclusion is supported by a number of experiments from different laboratories. The difficulties of determining the hormone content of any preparation are thus increased, since this can be done accurately only when the animal's own hypophysis is eliminated through hypophysectomy. This does not disparage the use of normal animals for such experiments, however, as these are a vital necessity in gaging the therapeutic value of such preparations, but it does suggest the necessity of basic work under carefully controlled conditions, and such conditions are not obtainable in the normal animal, its own hypophysis being the disturbing factor.

In judging the value of these preparations the "gonad-stimulating potency" has been one of the main tests. In the rat this potency is measured by the weight of the ovaries produced, great potency producing heavy ovaries, filled mainly with luteal tissue. The luteinizing hormone, which brings about this result, checks ovogenesis and the growth of follicles (Swezy, 1933a) and produces ovaries having a tumor-like metabolism (Szarka et al., 1933). In the normal animal the corpora lutea, so far as present data indicate, have little or no function beyond inducing the secretion phase in the uterus and the maintenance of pregnancy. It is therefore a serious question of what value the administration of the luteinizing hormone, which has, as its chief function, the induction of the formation of this luteal tissue, may be in the nonpregnant individual. Its disadvantages would seem to outweigh any possible benefits. On the other hand, the hormone which stimulates the growth of the follicles, resulting in the secretion of folliculin with its reaction on the hypophysis itself, would seem to have a greater value as a therapeutic agent. This aspect of the effects of the "gonad-stimulating hormones" needs further study before the clinical importance of these preparations can be adequately tested, and some other criterion must be found for evaluating the extracts which will not stress the luteinizing hormone as the important one, a position which it holds in present methods of testing them for potency. In this connection the suggestion of Leonard (1933), that pregnancy extracts should be combined with the hormones of the hypophysis when "great ovarian stimulation" is desired, further emphasizes the need of caution on this point, as the desirability of ever producing such great ovarian

stimulation is open to very grave doubt. These heavy ovaries contain abnormal masses of luteal tissue, derived mainly from atretic follicles, and thus represent a pathologic condition which would seem to have little therapeutic value.

CLINICAL AND EXPERIMENTAL

THE COMBINED EFFECTS OF BILE SALTS AND OLEIC ACID ON CHOLERESIS*

FRANK WANG CO TUI, NEW YORK, N. Y.

THE word "choleresis" is here used in the sense advocated by Brugster and Horster.¹ It stands in the same relation to the secretion of bile that the word "diuresis" does to the secretion of urine. A substance that increases bile production is, according to this terminology, called a diuretic as contradistinguished from a cholagogue, a substance that promotes the expulsion of bile.

That bile salts, when absorbed, stimulate the further production of bile, has been established beyond reasonable doubt by Schiff,² Rosenberg,³ Okada,⁴ Foster, Hooper and Whipple,⁵ Specht,⁶ Mellanby,⁷ and numerous others after them, prominent among the recent workers being Chabrol⁸ and his collaborators.

The work of Doyen and Dufourt,⁹ showing that soap causes a slight diminution in the bile secretion during the first twenty-four hours, prompted Okada⁴ to investigate the effect of sodium oleate as a cholagogue. He found that sodium oleate, after ingestion, exerts quite a powerful stimulating effect on bile production. Chabrol and Charonnat⁸ found that oleic acid as well as sodium oleate administered both intravenously and into the duodenum caused a marked choleresis.

As far as could be determined from a review of the literature, little work of any consequence has been done on the potentiation of one cholagogue by another on experimental animals. Meissner¹⁰ investigated the effects on bile

*From the Laboratory of Surgical Research, New York University, and Bellevue Hospital Medical College.

Received for publication, March 16, 1933.

secretion of salicylic acid and the sodium salt of cinnamic acid and of benzoic acid and theobromine salicylate. Finkelstein and Lipschutz¹¹ showed on human subjects with the aid of the duodenal tube, that when bile salts were injected into the duodenum, the biliary output as compared with control periods averaged 91 per cent; but that when oleic acid was administered with the same dose of bile salts the increase was over 143 per cent. Under their experimental conditions, however, it was impossible to eliminate the cholagogue factor of both the substances used.

The purpose of the work to be reported below is to determine whether relatively small doses of bile salts combined with small doses of oleic acid, cause a larger flow of bile than when these two cholagogues are given separately.

EXPERIMENTAL PROCEDURE

Twenty-four picked animals were used in this investigation. They were all healthy, young adults, all weighing 15 kilograms at the time of the experiment. The food was the stock feed of scraps, used in the laboratory kennels, and given twenty-four hours before the experiment. All the animals were anesthetized with nembutal* (pento-barbital) 750 mg. per dog, given intravenously ten minutes before the operative preparation. In order to insure a uniform anesthesia, each animal was given 100 mg. more of nembutal each hour after the initial dose, until the termination of the experiment.

The operative procedure was similar to that used by Chabrol.⁸ The abdominal cavity was opened through a midline incision. The common duct was cannulated, and the cannula connected with a rubber tubing through a U-shaped glass tube after the method of Rous and McMaster.¹² The rubber tube was then made to project out of the abdominal cavity into the collecting vessel. The gallbladder was segregated by a ligature around the common duct. For the instillation of the cholagogues into the duodenum, a moderately rigid rubber tube was introduced through a small opening on the anterior wall of the pylorus into the duodenum. This tube was anchored to the pyloric wall by a purse-string suture and was just long enough to project out of the abdominal cavity. When not in use, it was kept closed with a screw clamp. The abdomen was closed around the two outjutting tubes at the completion of the operation.

Specimens of bile were collected every half hour until a level or a downward trend in the amounts for three successive periods was obtained before the cholagogue substances were instilled through the tube leading into the duodenum. In some experiments this level or downward trend was attained in four collections, in others, in five, or six collections. Inasmuch as this time variation was evenly distributed in the three series, it was not taken into consideration as a possible source of error.

The collection after the instillation of the cholagogues was continued for three more periods. This was done because in preliminary experiments it was found that under the above experimental conditions and in the doses of cholagogues used, the increased bile flow was evident in the first three half hour

*Grateful acknowledgment is made of the nembutal kindly furnished us by the Abbott Laboratories, New York, New York.

collections after administration, and that in the fourth period the yield was back to nearly that of the period immediately before the administration. The total collection of the three postinstillation periods, was, therefore, deemed to be a faithful representation of the increased choleretic induced by the choleretics. The amounts collected during the three half hour collections prior to the instillation of the choleretics were used as the controls.

The twenty-four experiments were divided into three series of eight experiments each. The first eight dogs were given bile salts in the dosage of 150 mg. each of sodium taurocholate and sodium glycocholate, in 10 c.c. of water. The second series were given 3 c.c. of oleic acid with 7 c.c. of water, and the third series 150 mg. each of sodium taurocholate and sodium glycocholate, plus 3 c.c. of oleic acid and enough water to make up to 10 c.c.

The protocols are reproduced in table form (Tables I, II, and III).

DISCUSSION

It will be seen from Table I that in this series five showed a rise after the administration of bile salts, while three showed a fall. Thus bile salts failed

*150 mg. each of sodium taurocholate and sodium glycocholate administered into the duodenum after the first three collections.

as a choleretic in 37.5 per cent of the experiments. In the former group the highest yield was 85.7 per cent above the control period. The average of the total of the three collections after administration in the eight experiments was 18 per cent above that preceding administration.

Of the eight experiments in Table II, again five showed a rise after oleic acid and three showed a fall. The percentage failure is here the same as in Series I. The highest percentage rise in this group was 100 per cent, and the average of the total of the three half hour collections after the administration was higher by 18.3 per cent than that of the same periods before. It is apparent that the dose of bile salts and of oleic acid used here had about the same choleretic power.

*150 mg. each of sodium taurocholate and sodium glycocholate plus 3 c.c. oleic acid.

experiments (100 per cent) showed an increase in bile output after the administration of the combined cholagogues. Three experiments showed yields of over 100 per cent: Exper. III with 289.5 per cent; Exper. IV with 205.4 per cent, and Exper. II with 195.2 per cent. Any one of these three figures exceeds the sum of the highest yields in Series I and II. The average of the total of the collections after the administration was 97.5 per cent higher than that of the same period before. This percentage is almost three times the sum of the two corresponding figures in Series I and II.

It is thus seen that the combination of the two cholagogues potentiate each other to a remarkable degree, whether judging from the number of experiments in each group in which a rise was registered, the percentage rise of the individual experiments in the three different series, or the ratio between the average of the total yield before and that after the administration. The potentiation is so striking as to merit the term synergism.

SUMMARY

In three series of experiments of eight experiments each, on the dog, in which the weight factor, the diet, the anesthetic level, and the dose of cholagogics given were kept constant, it was shown that choleresis caused by the combination of relatively small doses of oleic acid and of bile salts was much more marked than would be expected from the sum of the effects of the same doses of bile salts and oleic acid administered separately.

THE RELATIVE EFFECTS OF DIATHERMY AND INFECTION ON THE PLASMA PROTEINS, PLASMA VISCOSITY AND SUSPENSION STABILITY OF THE BLOOD IN DOGS*

JOHANNES K. MOEN, M.D., GRACE MEDES, Ph.D., AND I. CHALEK, B.S.,
MINNEAPOLIS, MINN.

THE beneficial effect of fever in the defense mechanism against infection was reviewed in a recent report by Reimann.¹ He also showed that an increase in plasma viscosity depending on an increase in the fibrinogen and globulin fractions of the blood enhanced specific agglutination and suggested that these protein changes which occur during infectious diseases play an important rôle in immune processes. In a previous study on lobar pneumonia² a prompt increase in the plasma globulin and fibrinogen fractions together with increased plasma viscosity was observed within a short time after the initial chill. It

seemed possible that the high fever associated with this disease together with the severe toxemia may have been an important factor in inducing these blood protein changes.

Recent publications indicate an increasing use of artificial fever in the treatment of various diseases. The tendency toward the substitution of diathermy for the older and more difficultly controlled methods of inducing therapeutic pyrexia by infections or by the injection of foreign proteins necessitates inquiry as to how far increased body temperature resulting from diathermy duplicates the effects of fever due to infection or to the injection of foreign protein.

The object of the present study is to compare the relative effects of pyrexia produced by diathermy on the plasma proteins, the plasma viscosity and the suspension stability of the blood with the changes produced by experimental infectious fever of comparable duration. A search of the literature revealed that comparatively few observations have been made on the influence of diathermy and the ultra high frequency current on the blood proteins. Frisch and Starlinger³ and Hirsch⁴ observed slight changes in the blood proteins after local diathermy for short periods. Knudson and Schaible⁵ noted a slight increase in the total blood proteins of dogs heated by the ultra high frequency current.

METHODS

The first experiments were made on rabbits, but it was found that these animals succumb rapidly after being heated by diathermy. Dogs weighing from 10 to 16 kg. were then used. Nembutal (sodium-ethyl, 1-methyl-butyl barbiturate) in an initial dose of 30 to 40 mg. per kg. of body weight was given intravenously as a sedative. The effect of this drug lasted from four to eight hours. If subsequent restlessness occurred smaller supplementary doses were given subcutaneously. Nembutal anesthesia was also employed before intraperitoneal and intra-bronchial inoculations. This drug had but slight effect in reducing the normal temperature in an occasional dog. In one animal, a maximum reduction of 1° C. occurred in five hours.

During the diathermy treatment, the anesthetized animal was suspended in a hammock with its head supported in a sling. Excessive loss of body heat and moisture by respiration was prevented by the inhalation of steam rising from a basin of hot water on an electric plate under the dog's head, which was covered by a hood. Rectal temperature was measured at one-half to one hour intervals. Water was supplied through a stomach tube. The animals were weighed before and after treatment. The Fischer diathermy machine, type CDC with a spark gap oscillator of an approximate frequency of 1,000,000 cycles was used. Copper gauze electrodes 10 by 15 cm. sewed to cotton pads 1 cm. thick and soaked in a sodium chloride solution were fixed with bandages to the shaved sides of the dog. A current density of approximately 10 milliamperes per square centimeter of electrode area was employed to raise the dog's temperature to the desired degree. The amount of current necessary to maintain the temperature at a certain level varied in different animals.

In order to produce a severe infection with rapid onset which would be accompanied by a fever, similar in degree to the pyrexia evoked by diathermy,

peritonitis was caused by the intraperitoneal injection of 5 to 15 c.c. of a saline suspension of dog feces (5 gm. per 15 c.c. suspension). In two instances, 3 c.c. of an eighteen-hour blood broth culture of Type I pneumococcus in 16 per cent gelatin solution were injected intrabronchially in an attempt to produce a pneumonia. In one animal, 3 c.c. of a Type I broth culture of pneumococcus were injected intrapleurally, and another was injected intraperitoneally with 10 c.c. of a broth culture of *B. welchii*.

Twenty to 25 c.c. of blood for analysis were withdrawn from the jugular or leg veins with a minimum of stasis, and oxalated. In some instances in which the animals were moribund blood was obtained by cardiac puncture. Plasma protein fractions were determined by Berglund's⁶ modification of Howe's method using sodium sulphate as a salting-out agent. Nitrogen determinations were made by the micro-Kjeldahl technic. The sedimentation time of erythrocytes was determined in a manner similar to that described in a preceding paper.² The longer sedimentation time of normal dogs' blood as compared to that of human blood is possibly due in part to the lesser amount of blood protein and the greater number of erythrocytes in dogs' blood. The viscosity of the plasma, and in several instances the viscosity of the whole blood was measured with the Hess viscosimeter. Corpuscle and plasma volume determinations were made by centrifugation of blood in a tuberculin syringe at 2,000 revolutions per minute for one-half hour.

RESULTS

Effect of Pyrexia Produced by Diathermy on the Protein Fractions and Viscosity of the Plasma.—Eight dogs were heated with diathermy for variable periods of time. Pyrexia usually developed within one hour after starting diathermy. The duration of the fever was ten hours in three dogs, eight hours in two dogs and nine, eleven, and twelve hours in each of three dogs, respectively. The maximum temperature attained in the animals varied from 40.5° C. to 42.5° C. The four dogs heated to the highest temperatures died shortly after completion of the experiment. One dog heated to a maximum of 41° C. with an average temperature of 40.5° C. for ten hours, died about eighteen hours after completion of the experiment. The other three dogs heated for eight, ten, and twelve hours survived. When the desired temperature had been reached in several of the dogs, diathermy was discontinued and the temperature was maintained at a fairly constant high level by the inhalation of steam; for instance, after raising the temperature in one animal, diathermy was discontinued and the temperature was maintained between 41° C. and 41.3° C. for nine hours by steam inhalation. In several dogs, intermittent use of diathermy was sufficient to maintain pyrexia.

The effect of pyrexia produced by diathermy on the total plasma protein was variable (Table I). In two dogs (3 and 5) an increase in amount occurred within a few hours and in six dogs a decrease was noted. The total globulin fraction was decreased in five dogs and only slightly increased in three (3, 4, and 13). The amount of fibrinogen was decreased in four instances (2, 3, 12, 13) and slightly increased in four (1, 4, 5, and 6). The most constant changes in the

plasma protein fractions were a slight increase in amount of albumin and a corresponding decrease of total globulin. The viscosity of the plasma was usually unchanged.

Effect of Severe Rapidly Fatal Peritonitis on the Protein Fractions and Viscosity of the Plasma.—Six dogs were injected intraperitoneally with 5 to 15 c.c. of a saline suspension of dog feces. Four of the six dogs were moribund within twelve hours. Blood proteins were determined usually before and from eight to twelve hours after the fecal injection. Five of the six dogs developed fever about three hours after the fecal injection with maximum temperature between 40.6° C. and 42° C. One animal developed no fever and died in a condition of shock eight hours later.

The total plasma proteins were slightly increased (Table II) in four animals and slightly decreased in two during the first twenty-four hours. The fibrinogen was appreciably increased in two animals (9 and 10), decreased in one (14) and remained unchanged in three (4, 8 and 12) during twenty-four hours. In Dog 12, the total protein increased to 6.35 gm. and the fibrinogen to 0.82 gm. five days after infection. There was a slight increase in the albumin fraction in five dogs and a slight decrease in the total globulin fraction in three. The euglobulin and pseudoglobulin fractions were variable.

Only slight changes in the plasma viscosity were noted in these six animals. The viscosity of the whole blood in Dog 10 before and after infection was found to be 4.9 and 8.2, respectively. The increase was due apparently to the marked increase in red cell volume from 33 to 62 per cent.

Effect of Prolonged Infections on the Plasma Proteins and Viscosity of the Plasma.—Three dogs were used. A number of procedures were carried out on two of the animals. Dog 6 was injected intraperitoneally with 15 c.c. of a suspension of feces. This was followed by a fever of 40.4° C. The animal recovered rapidly and the next day the temperature was normal. Unfortunately the blood specimen taken before the intraperitoneal injection was accidentally discarded. However, twenty-four hours after the fecal injection the blood protein fractions were within normal limits as shown in Table III. Two days later or three days after the fecal injection, marked changes in the blood proteins were observed. The total plasma protein increased from 5.60 gm. per 100 c.c. to 8.51 gm., the fibrinogen from 0.54 gm. to 3.44 gm., the total globulin from 2.62 gm. to 5.48 gm. while the amount of albumin did not change. Ten cubic centimeters of a brain broth culture of *B. welchii* were then injected intraperitoneally, and twenty-four days later 3 c.c. Type I pneumococcus in 16 per cent gelatin solution were injected intrabronchially with no apparent effect on the animal. After fifty days the fibrinogen and total globulin were still increased, although reduced from the maximum figures observed three days after the fecal injection. The red cell volume in this dog varied from 22 per cent to 56 per cent, the higher values occurring during periods of fever. The viscosity of the plasma was increased from 1.70 to 1.90 during the period of high total globulin and fibrinogen.

In Dog 11, 3 c.c. of an eighteen-hour blood broth culture of Type I pneumococcus in a 16 per cent gelatin solution were injected intrabronchially in an attempt to produce pneumonia. Practically no fever developed and the next

day the dog appeared well. At the end of four days, during which time the temperature was normal, the blood fractions showed only minor changes. Three cubic centimeters of Type I pneumococcus broth culture were then injected intrapleurally. One-half hour following the intrapleural injection, the animal developed a severe chill, but fever did not develop. Seven days after the intrapleural injection, marked changes in the blood proteins were observed with increase in the total plasma protein, the total globulin and fibrinogen. The fibrinogen especially increased, rising from 0.63 gm. to 1.50 gm. After a period of seven days, 5 c.c. of a fecal suspension were injected intraperitoneally, following which the animal developed a fever reaching 40.4° C. Twenty-four hours later the dog was moribund and died shortly after blood was taken for analysis. The albumin fraction was increased and the total globulin fraction decreased as in the preceding experiments in which peritonitis was produced. In spite of the total globulin decrease, the fibrinogen showed further increase to 1.63 gm.

Dog 15 was injected intraperitoneally with 15 c.c. of a fecal suspension. A maximum temperature of 41° C. was reached four hours later, but the next day the temperature returned to normal. The changes in the plasma proteins, erythrocyte volume and plasma viscosity (Table III) were similar to those described in Dogs 6 and 11. The total plasma protein and fibrinogen had decreased by the end of ten hours but two days later both were increased, especially the fibrinogen. On the other hand, the total albumin increased slightly and the total globulin diminished. The viscosity of the plasma was greatest at two days when the fibrinogen was at its height.

Effect of Pyrexia Produced by Diathermy and by Infection on the Sedimentation Time and Red Cell Volume Percentage.—A constant increase in the sedimentation time of erythrocytes was noted during fever whether it was produced by diathermy or by infection. A numerical value for the sedimentation time was not possible in many instances as the red cell volume did not settle to the arbitrary level used in our method. The increased suspension stability of the blood was probably accounted for by the increase in red cell volume percentage which many have shown to have a direct bearing on erythrocyte sedimentation. The erythrocyte volume was increased 5 to 55 per cent above the normal during diathermy heating and 43 to 100 per cent above the normal during fever of infectious origin. The sedimentation time approached normal in the animals that survived diathermy heating when the red cell volume percentage dropped to its former level. In the animals with prolonged infections, the sedimentation time was shortened when the cell volume was normal and the globulin and fibrinogen fractions increased.

DISCUSSION

In drawing conclusions from our findings, attention must be directed to the fact that strictly comparable conditions could not be obtained in the three sets of experiments because of the inability of the animals to survive the desired degree and duration of pyrexia produced by diathermy. Therefore no measurements have been made of the protein fractions of the dogs heated with diathermy after the length of time that had to elapse before a significant change had taken place

in the dogs which had infectious fever. The marked increase in red cell volume percentage during fever with probable decrease in total blood and plasma volume also added complicating factors.

In Table IV are recorded the mean values of rectal temperature, plasma viscosity, total plasma protein, and the various protein fractions during the control periods and the three experimental periods, together with the probable errors

of the means. In Table V are the ratios of the differences of the means to their probable errors computed for the control periods (a) and of the three experimental periods (b). According to statistical standards, when this ratio is greater than 3 the difference between the means becomes of significance, when approximately 3 it is of doubtful significance, and of no statistical significance when less than 3.

Increase of total protein was apparently not dependent upon elevated temperature, since the group subjected to diathermy, in which temperature was definitely raised, showed no rise in plasma proteins and in the group with prolonged infection, the proteins rose while the rise in temperature was only slight. In the case of the rapidly fatal infection, with high fever, the total protein was

TABLE V

Mb - Ma

$$\sqrt{PE_{Mb}^2 + PE_{Ma}^2}$$

	CONTROL (A) DIATHERMY (B)	CONTROL (A) RAPIDLY FATAL IN- FECTION (B)	CONTROL (A) PROLONGED INFECTION (B)
Rectal temperature	+ 12.63	+ 16.05	+ 3.50
Plasma viscosity	- 1.93	+ 1.84	+ 7.76
Total protein	- 0.98	+ 4.26	+ 4.85

Total globulin	- 1.20	- 0.11	+ 3.00
Albumin	+ 0.88	+ 1.53	+ 2.64

higher than normal. It seems then that elevation of the total protein level in these experiments was associated with infection regardless of type and not with pyrexia.

The increase in total protein was not associated invariably with increase of either fibrinogen, albumin, or total globulin. In the case of the rapidly fatal infection the reaction of each group was so variable that none showed a significant rise, whereas, in the prolonged infection, the ratios of the differences of the means to their probable errors recorded in Table V indicate that the rise in value of the fibrinogen is of definite statistical significance, and the increases in both albumin and globulin approach significant ratios. These findings are in accord with those of Hurwitz and Meyer⁷ and others who showed definite increases in the globulin fraction during various immunization processes in which fever was not a prominent feature.

Plasma viscosity was moderately increased only in the group with prolonged infection. Its rise was, therefore, not associated with a high fever but with a high fibrinogen and total globulin content of the blood as seen also from inspection of individual cases in Table III.

The concentration of the blood with marked increase in the red cell volume percentage following artificial heating of dogs has been observed by others.⁵ The total blood volume was found to be definitely decreased during heating with the ultra high frequency current⁵ and with diathermy.⁸ That these changes cannot be accounted for on the basis of general body dehydration was indicated by our experiments in which loss of body weight was prevented by the giving of water by stomach tube and by the inhalation of water vapor. Some of the animals gained slightly in weight during diathermy heating due to excessive water intake. It would appear that a redistribution of the plasma with a shift from the blood to the tissue spaces had occurred.

Interpretation of the sedimentation times of erythrocytes in regard to their correlation with the plasma protein changes was difficult of analysis because of the marked increase in the red cell volume during fever. The increase in the suspension stability of the blood during fever in dogs appeared to be directly proportional to the percentage increase of erythrocyte volume. Others⁹ have also found an increase in suspension stability during diathermy heating, while Bernet,¹⁰ on heating rabbits for shorter periods, found no change.

SUMMARY

1. Slight and variable changes were produced in the plasma protein fractions of dogs by pyrexia due to diathermy over periods of from eight to twelve hours. In general, the changes were in the direction of a reduction, but in no case did this reduction attain a statistically significant value.

2. During infectious fevers of short duration the total protein was definitely elevated, but the shifts in the individual fractions were so variable that in no single fraction was the rise significant.

3. In certain prolonged infections even without marked rise of body temperature the total protein was definitely elevated. Albumin, total globulin and fibrinogen were all increased in amount, the rise in fibrinogen being most marked.

4. The only significant change in plasma viscosity was in the group with prolonged infection. Here the viscosity was moderately increased and was probably dependent on the high fibrinogen and globulin content of the plasma.

5. Correlation of changes in the erythrocyte sedimentation time with fractional plasma protein variations in these experiments were difficult of analysis because of the marked increase of the erythrocyte volume in dogs during fever.

6. Although conditions of the three sets of experiments were necessarily not identical, it is suggested from our data that fever alone is not an important factor in evoking the plasma protein changes usually observed in infectious diseases.

DESTRUCTION OF PYOGENIC BACTERIA IN THE ALIMENTARY TRACT OF SURGICAL MAGGOTS IMPLANTED IN INFECTED WOUNDS*

WILLIAM ROBINSON, PH.D., AND VERNON H. NORWOOD, M.D., WASHINGTON, D. C.

IN THEIR natural surroundings, blowfly larvae feed upon dead and decaying animal tissue. When used clinically, that is, when bred aseptically and implanted as sterile maggots in infected wounds, they function largely to remove dead tissue and pus from the wound. At the same time the maggots take up large numbers of bacteria from the wound and by destroying them aid in reducing the infection.¹⁴

The present investigation was made to determine the relative abundance and viability of the bacteria in the successive regions of the alimentary tract.

*Contribution from the Division of Insects Affecting Man and Animals, U. S. Bureau of Entomology, Washington, D. C., and the Pathological Laboratory of the Church Home and Infirmary, Baltimore, Md.

Received for publication, June 12, 1933.

This was done by means of dissections and bacteriologic cultures. The species used was *Lucilia sericata*. A description of the technic and apparatus, particularly that used in the aseptic dissections, is included, as descriptions of special methods are sometimes of interest.

DISSECTIONS AND CULTURES

Description of the Digestive Tract.—The tract is tubular, highly convoluted, and very long, being 90 to 95 mm. in length, or six to seven times longer than the full-grown maggot. To the short and very narrow esophagus is attached a sac for holding food in reserve. This lies along the back and when containing food is visible through the integument. The stomach is unusually long, generally 60 to 65 mm. and comprising two-thirds of the entire tract. It is divided histologically and functionally into three sections, the fore-, mid-, and hind-stomach. It extends from the enlargement at its junction with the esophagus posteriorly to the malpighian tubes. The intestine is about 30 mm. long and extends from the malpighian tubes to the anus. Greater details may be found in descriptions by Hobson,⁹ Lowne,¹¹ and Snodgrass.¹⁶

Technic of Dissection.—The maggots were reared under the usual sterile conditions,^{4, 5, 6, 12, 13, 17} to about $\frac{1}{4}$ to 6 mm. in length, the size suitable for introduction into wounds. The sterile maggots were implanted in osteomyelitis wounds and allowed to feed. In twenty-four to forty-eight hours they were large enough to dissect and meanwhile the food had passed freely through the tract. The maggots were then removed and killed by momentary dipping in boiling water. Their external surface was sterilized by immersion for fifteen minutes in mercuric chloride disinfectant,^{4, 13, 18} and washed in two changes of sterile saline. The sterility of the external surface was confirmed with cultures which showed no growth. The sterility of the alimentary tract had likewise been confirmed before the maggots were implanted in the wounds. The maggots were ready for dissection within thirty minutes of removal from the wound.

Dissections were made under a binocular microscope. Each specimen was opened under sterile saline in a Petri dish, and aseptic technic was used throughout. In opening the maggots, a pair of fine dissecting scissors, with the cutting edges at an angle with the handles, was found to be the most satisfactory. The extreme points of the scissors were taken off with an abrasive to prevent piercing the intestinal tract. Forceps with fine curved points were used in making the dissections.

When uncoiling the alimentary tract and disconnecting it from the branching tracheas, especial care was taken to avoid rupture of the tract and consequent contamination of the saline. Notwithstanding this, rupture occurred frequently and the specimens had to be discarded. As an additional precaution against contamination through any possible rupture, dissections were begun upon the intestine, which always had the least infection, and the fore-stomach was removed last. Approximately 20 mm. of each portion was removed. The sections were cut off above the saline with a red-hot platinum wire in order to sear the remaining ends of the tract and thus prevent contamination of the saline.

Cultures.—In the series comprising Table I, the cultures were made by macerating and smearing the various sections of the tract upon the surface of blood agar plates. Those in Table II were macerated in nutrient broth tubes. A control culture of the saline in the dissecting dish was made in each case after the maggot had been opened but before dissection of the tract.

RESULTS

Dissections were made successfully of 51 individuals. Because of the decisive nature of the results and also because of the difficulty in dissecting without rupture the delicate and numerous convolutions of the tract, the experiments were limited to this number.

In cultures from the intestine, no bacterial growth at all was observed in 26 of the specimens listed in Table I. In the two remaining specimens a slight growth was found but at the same time the saline also showed contamination before dissection was begun.

*The number of plus signs indicates the relative density of growth. One indicates ten or less colonies, and four represent one hundred or more colonies. Sections of tract were only approximately of equal length.

The hind-stomach was also found to be sterile in 17 specimens. The remaining 11, among which were the two cases above mentioned, showed slight growth.

In every case bacterial growth was obtained in cultures from the fore-stomach; and in all but two instances the growth was abundant. The relative degree of growth is indicated in all cases by the number of plus signs, from one to four.

*Degree of growth in this medium cannot be shown because a general clouding of the broth takes place.

A more rigid test was made in the second series when dissections were cultured in nutrient broth. In this medium the presence of even minute numbers of bacteria becomes evident in the clouding of the broth.

The sterility of the intestine and the presence of bacteria in the fore-stomach, indicated in the first series, were confirmed in every instance. The results are shown in Table II.

DISCUSSION

Disappearance of Bacteria in the Stomach.—It has been shown that, in their course through the alimentary tract of the maggot, bacteria become reduced in numbers and finally disappear. It is evident, from the sterility of the intestine, that the bacteria are destroyed in the stomach. It is also apparent that this action takes place principally in the posterior portion of the stomach. The destruction of bacteria in this way is probably a factor in the general disinfection of the wound under the maggot treatment, as noted by Baer³ and confirmed by others.

The species of bacteria encountered in the experiments were a betahemolytic streptococcus and a hemolytic type of *Staphylococcus aureus*. Cases were selected in which no organisms of the proteus type were present. This was because of the difficulty of making quantitative estimates of the numbers of bacteria

present with those spreading varieties. Hobson¹⁰ has made an examination of the general bacterial content of the alimentary tract of nonsterile maggots which had fed under normal conditions.

Results somewhat similar to those of the present investigation were reported by Duncan,⁷ who referred to some experiments of his own and of others in which destruction of certain species of bacteria was found to take place in the alimentary canal of flies.

Bacot,^{1, 2} Glaser,⁵ and Smith-Graham,¹⁵ however, using flies of the family Muscidae, found that bacteria ingested by the larvae with their food persisted through metamorphosis and appeared in the intestine of the adult flies. This may indicate that the larvae of those species are unable to destroy all bacteria within the alimentary tract. It seems possible, however, that the adult tissues may have become inoculated from the bacteria which were still present in the fore-stomach of the maggot at the time of pupation. By means of a special technique, Wollman¹⁰ was able to rear adult flies free from infection.

The disappearance of the bacteria between the fore-stomach and the intestine, in the region of greatest activity of proteolytic enzymes, according to Hobson,⁹ indicates that the bacteria are destroyed by digestion.

SUMMARY

A study has been made of the relative abundance and viability of bacteria in the various sections of the alimentary tract of surgical maggots used to hasten healing of infected wounds. The investigation was made by means of dissections and bacteriologic cultures.

The results are given in tabular form and show that large numbers of the bacteria taken in with the food were destroyed in passing through the long, tubular stomach of the maggot. Complete destruction of any remaining organisms occurred in the intestine, for no viable bacteria were found in any cultures of the intestine.

The results are discussed in connection with the work of others of a somewhat similar nature.

A description is given of the method used in making the aseptic dissections.

BENIGN ADENOMA OF THE SWEAT GLANDS*

E. BIRCHWOOD, M.D., CHICAGO, ILL.

PINGAUD¹ in 1877 reported a sudoriparous adenoma of the scalp. His gross and microscopic study was given in detail. He gave the impression that it was a small elastic fibromatous mass which was smooth and shining. There was no definite line of demarcation between the tumor and the skin. The histologic examination showed that the skin covering the tumor was intact and was separated from the neoplasm by a layer of normal connective tissue. It was lobulated like a gland. Each lobule contained a small amount of fibrous stroma composed of connective tissue. The stroma circumscribed an elongated or rounded network which contained epithelial cells. There were no epithelial pearls. In 1881 Sangster² reported a papillary tumor of the scalp. The gross and histologic study gave a picture similar to that of Pingaud. Mulert³ in 1897 called this type of tumor an endothelioma. Aimes and Paulet⁴ in 1921 gave a description of massive sudoriparous adenoma of the scalp which was very similar to that of Pingaud. Dupont and Delarue⁵ in 1928 described a sudoriparous tumor, but it was of the type which communicated with the exterior.

This case is presented because so few have been described in the literature, and because it has been designated by various authors as "benign epithelioma," "adenoma of the skin," "endothelioma," and "papillary tumor" of the scalp. This tumor was removed from over the right parietal bone. The growth first appeared about ten years previous in a man sixty-two years old, and had regularly and slowly increased in size without causing any

*Received for publication, April 26, 1933.

pain. The specimen weighed 37 gm. and measured 6 by 4 by 3 cm. It was oval with a short stalk-like attachment that had been resected and measured 2 by 2 cm. at this lower stalk attachment margin. There were a few grayish hairs extending along the cut margin. The rest of the surface was hairless, white, and smooth. The tumor was well-encapsulated and numerous cut surfaces were white and homogenous. There was a general firmness with consid-

Fig. 1.—Sixteen mm. obj., showing lobulation with epidermis and dermis.

Fig. 2.—Four mm. obj. Cord-like arrangement of epithelial cells. Palisaded cells of periphery of lobules.

erable elasticity. Microscopic examination showed an epidermis with rather thin stratum corneum, a poorly defined stratum granulosum and a Malpighian layer with a lack of tendency to form definite intercellular bridges. The dermis consisted chiefly of connective tissue with sparse blood vessels. The tumor proper had well-formed cord-like arrangement of epithelial cells and some lobulation simulating glands surrounded by connective tissue. These lobulated groups were filled with cells, the major portion of which were flat and

oval; however, round and spindle-shaped types could be seen. A few contained elongated nuclei surrounded by mitochondria. Those in the periphery were palisaded with connective tissue as a base. The central cells in the large lobules were arranged indiscriminately.

The possibilities as to the origin of this tumor are: (1) the basal layer of the epidermis; (2) the outer root sheath of the hair follicle; (3) the ducts and bodies of the sweat glands; and (4) the sebaceous glands. If we consider the views of Krompecher⁶ then the absence of fibrillation of the constituent cells and the lack of tendency to form definite intercellular bridges rules the first two possibilities out. This leaves for consideration the sweat glands and the sebaceous glands. At some places in the tumor there is a tendency to form a two-layered epithelium surrounding the central cavity, the outer being of the columnar sort and the inner layer showing a tendency toward the squamous type. The presence of the colloid-like masses in the epithelial cells here and

Fig. 3.—Four mm. obj. The colloid-like masses which have resisted solvents and were not differentiated by fat stain.

in the lumina gives the tumor a general resemblance to those tumors described^{7, 8, 9} as sebaceous gland tumors. These colloid-like masses, however, are obviously not of fatty nature because they resisted not only the solvents used in embedding but were ruled out by fat-staining methods and subsequent treatment of the section.

7018 CREIGIER AVENUE

INTRACUTANEOUS REACTIONS INDUCED IN GUINEA PIGS INOCULATED WITH *B. ABORTUS**

A PRELIMINARY REPORT

H. GLADYS DACEY, B.S., AND NATHAN KOROVIN, M.S., NEW YORK, N. Y.

THE diagnosis of undulant fever is particularly difficult because of the marked variation in clinical manifestations, and, consequently, may be quite dependent upon laboratory tests. As microorganisms of the *abortus-melitensis* group are demonstrated in the blood stream with difficulty, cultural examinations are of limited value. At present, the agglutination test, which is in general use, is considered relatively specific, although the reactions obtained may, in some cases, be due to a past infection. On the other hand, Montagnani,¹ Burnet,² Tramontano,³ Carpenter and Boak,⁴ Giordano and Sensenich,⁵ and Gilbert and Dacey⁶ have reported failure to obtain agglutination in sera from patients having undulant fever. In view of these findings, an intracutaneous test might furnish valuable information.

Burnet,⁷ Trenti,⁸ and Dubois and Sollier⁹ obtained specific reactions with broth filtrates, while Montagnani,¹ Fornaca and Bua-Fazio¹⁰ and Giordano,¹¹ on the other hand, failed to do so. Fornaca and Bua-Fazio,¹⁰ Mitra,¹² Canale,¹³ de Fermo,¹⁴ Giordano,¹¹ Simpson and Frazier,¹⁵ and Levin¹⁶ report specific reactions with heat-killed suspensions of the microorganisms. Schoenholtz and Meyer¹⁷ found that "cutaneous hypersensitiveness in *abortus* infected guinea pigs may be demonstrated by testing the infected animal intracutaneously with filtered cell solution of *B. abortus*. The substance precipitated by acetic acid in the cold at P_H 3.5 to 4.0 elicits allergic reactions as effectively as the original solution." In 1931, Leavell and Amoss¹⁸ published a report of a study of the endermic reaction in *Brucella* infections in which various extracts and suspensions including a so-called "specific soluble substance" were tested. They found none which they considered definitely specific. Human subjects were used for the investigation. A species of animal not subject, under normal conditions, to infections with members of the *abortus-melitensis* group may be found more suitable for purposes of control than persons who may have had undulant fever which was undiagnosed or an infection which was subclinical in nature. One would judge

*From the Division of Laboratories and Research, New York State Department of Health, Branch Laboratory, 339 East 25th Street.

Received for publication, April 11, 1933.

from the information available in the literature that allergic reactions may be demonstrated for a number of years following recovery from such an infection.

The results of a preliminary study of this problem undertaken during 1931 may be of interest. A number of the authors mentioned have reported that the reactions with bacterial suspensions and with protein fractions have been very severe, in certain individuals, those with the former often being accompanied by more or less serious general symptoms. In our experience, the intracutaneous inoculation of heat-killed suspension has elicited a reaction in 18 of 22 guinea pigs infected with microorganisms of the abortus-melitensis group. The reactions have been very severe and characterized by congestion, edema, and marked necrosis. Eighty-eight presumably normal guinea pigs and 27 which had been inoculated with material submitted for the routine examination for tubercle bacilli were also tested. Four, or 3 per cent, showed slight nonspecific reactions.

"Abortin" prepared according to the method of Seyfarth¹⁹ not only failed to elicit reactions in certain guinea pigs known to have been infected with *B. abortus*, but induced reactions in some apparently normal animals. Tests were also performed with a concentrated and purified "abortin" prepared by precipitation of the protein with acetone, according to the method of Wadsworth and Quigley²⁰ for the concentration and purification of the toxin of the *Streptococcus hemolyticus*. Definite reactions were obtained in 8 of 10 guinea pigs known to have been infected with microorganisms of the abortus-melitensis group. Another guinea pig inoculated with the same culture gave no reaction, but since this animal died of intercurrent infection and the microorganism with which it had been inoculated was not recovered, the significance of the result is indeterminate. No reactions were obtained following the first inoculation in eleven apparently normal animals. Nonspecific reactions, possibly due to sensitization from the first series of tests, were observed in several of these guinea pigs upon reinoculation, one week after the first skin tests. With this material, as with the bacterial suspensions, the reactions were very severe, corresponding in this respect to the results reported by other workers. One guinea pig infected with microorganisms of the abortus-melitensis group reacted to the concentrated uninoculated broth used for purposes of control, as well as to the "abortin." The sensitivity of certain animals to protein derived from the medium has thus been demonstrated and necessitates careful control of all tests.

When this work was undertaken early in 1931, the study of intracutaneous tests in infections with microorganisms of the abortus-melitensis group had been restricted to bacterial suspensions, to culture filtrates, or to protein fractions of the bacteria. It therefore seemed important at that time to determine the activity of the carbohydrate fractions in an effort to find a less toxic antigen. Since the work of Heidelberger and Avery²¹ with the pneumococcus, specific soluble substances have been obtained from many other pathogenic microorganisms, such as the tubercle bacillus,²² the Friedländer bacillus,²³ the streptococcus,^{24, 25} *B. dysenteriae*,²⁵ *B. mallei*,²⁵ and the gonococcus.²⁶

A carbohydrate fraction was prepared by a modification of the method described by Wadsworth and Brown.²⁷

Seventy-two-hour cultures of a recently isolated strain of bovine origin (32219), grown on liver infusion agar, were killed by heating at from 60° to 65°

C. for thirty minutes. The growth was then suspended in 0.85 per cent salt solution. Two methods were used to disintegrate the cells. In one preparation, the suspension was made in 0.01 normal sodium hydroxide and boiled for one and one-half hours. The other was centrifugalized and the sediment resuspended in a very small amount of 0.85 per cent salt solution containing 0.2 per cent formalin. The latter was subjected to repeated freezing and thawing. In each case, after centrifugalization, the supernatant fluid was acidified with acetic acid to remove the protein and the carbohydrate substance was precipitated from solution with 95 per cent alcohol. The precipitate was dissolved in 0.85 per cent salt solution, acidified with acetic acid, and concentrated by boiling, any precipitate was removed, and the carbohydrate substance was reprecipitated by alcohol. This process was repeated until the acid coagulable proteins had been removed by acetic acid and the heat coagulable proteins by boiling. The final precipitate was washed with acetone and ether, and dried over calcium chloride in a vacuum desiccator. A protein reaction was not obtained by the biuret and xanthoproteic acid tests, and the Molisch test indicated the presence of carbohydrate. The amount of nitrogen in two preparations varied from 0.45 per cent to 0.56 per cent and the ash, from 12.24 per cent to 28.37 per cent.

Precipitating properties were demonstrated with *B. abortus* antiserum. Complement was fixed in the presence of immune serum. Intracutaneous inoculation of one of these preparations induced macular reactions, with no evidence of necrosis or sloughing in four guinea pigs infected with microorganisms of the *abortus-melitensis* group.

The results suggest that a carbohydrate substance extracted from microorganisms of the *abortus-melitensis* group may give reactions of a much milder character than those obtained with the whole microorganisms, or with a protein extract. Material which can be successfully used in skin tests on persons should give characteristic and specific reactions that are not very severe. A preparation of the protein and cleavage products, concentrated by the method of Wadsworth and Quigley,²⁰ might be entirely satisfactory for use in tests on animals, while the carbohydrate fraction, if the lack of toxicity which was observed is confirmed, would apparently lend itself more readily to a test for evidence of undulant fever in man.

Future work should be directed, first to the further purification of the carbohydrate substances, and, second, to a more extensive study of the intracutaneous reactions induced by those substances on animals and also on the human subject with a view to distinguishing the reactions of diagnostic significance; especially since carbohydrates which differ in their antigenic activity have been obtained from cultures of the pneumococcus.²⁷

THE SPECTROPHOTOMETRIC INVESTIGATION AND DETERMINATION OF BILIRUBIN*

WITH A CONSIDERATION OF OXYHEMOGLOBIN AND ITS EFFECT ON THE
ESTIMATION OF BILIRUBIN

GEORGE E. DAVIS, PH.D.,† AND CHARLES SHEARD, PH.D., ROCHESTER, MINN.

INTRODUCTION

VISUAL spectrophotometry has been employed in a number of investigations on bilirubin. In 1925 and 1926, Mann, Sheard, Bollman and Baldes¹³⁻¹⁷ obtained extensive spectrophotometric data bearing on the question of the sites of formation of bilirubin, the relative amounts of bilirubin formed at the different sites, and the formation of the pigment from hemoglobin. In 1926 and 1927, Bollman, Sheard and Mann investigated the absorption of bile pigment from the intestine² and the bilirubinemia following extirpation of the gall-bladder and ligation of the common bile duct.³ Spectrophotometric comparisons of the nature and amount of bile pigment found in the blood serum under normal and pathologic conditions were made by Magath and Sheard¹² in 1927. The effect of intravenous injections of chlorophyll on the rate of formation of bilirubin was investigated by Bollman, Sheard and Mann.⁴ In these researches the spectrophotometric data were obtained by means of a Keuffel and Esser "color analyzer," which allows transmissions to be determined visually in a spectral range extending approximately to wave length 430 m μ (millimicrons).

Various data and conclusions concerning the spectrophotometry of bilirubin have been published by Sheard, Baldes, Mann and Bollman.¹⁹ This work will be referred to later. Sheard, Mann and Bollman²⁰ have made spectrophotometric comparisons of purified bilirubin and the yellow pigment (bilirubin) found in bile and in blood serum and plasma. In both of these investigations fading of the pigment is demonstrated, the effects of hemolysis and turbidity are described and discussed, and the laws of Lambert and of Beer are shown to be applicable to solutions of the pigment. These investigations have amply demonstrated the sensitivity, accuracy and practicability of the spectrophotometric method of investigating bilirubin.

In this paper we shall present and discuss the applications of spectrophotometry to investigations on the bilirubin in the blood and in other body fluids. In addition we shall present some observations and experimental results concerning spectrophotometric determinations of oxyhemoglobin and the

effects of the presence of small amounts of this pigment on the quantitative determination of bilirubin.

The experimental data on which this article is based were obtained during the course of various investigations on bile pigment, concerning which a report will be made later. Our spectrophotometric observations are an extension of those made by Sheard and coworkers, to which reference has been made.

SPECTROPHOTOMETRIC THEORY AND ITS APPLICATIONS

To simplify the discussion we first review briefly some important principles of spectrophotometry and discuss their applications.

Consider a beam of light passing through a layer of solution of a substance X which is under investigation. Let I represent the intensity of the transmitted beam and I_0 the intensity which the beam would have had if it had been absorbed (in part) only by the solvent. Then the fractional part transmitted by X alone is $\frac{I}{I_0}$. Call this T , the transmission of X. Let C , L , ϵ and A represent the concentration, the thickness, the extinction coefficient (or absorption coefficient) and the absorption ratio, respectively. By definition, ϵ is the reciprocal of that thickness for which $T = 0.1$, while $A = \frac{C}{\epsilon}$, a constant.

It follows from Bouguer's law (commonly called Lambert's law) that

$$C = -\frac{A}{L} \log_{10} T. \quad (1)$$

If the value of A is known, this relation gives the concentration C upon substituting measured values of L and T . The expression $-\log_{10} T$ represents the optical density of X when measured in thickness L and concentration C .

It is easily shown from Equation (1) that for any one substance the ratio of the optical densities corresponding to any two wave lengths in the spectrum is a constant, regardless of the value of C or of L . Therefore, since no two substances have exactly the same transmission curve, a substance can be identified by showing that at various wave lengths the optical densities have the relative values known to be correct for that substance. Or, conversely, the entire transmission (or absorption) curve of a substance in solution can be calculated from the known values of the density ratios for the substance, if we know the value of T at some one wave length or can find it from the value of A and Equation (1).

In order that spectrophotometric observations on a solution may reveal only the absorption due to the dissolved substance, the absorption in the solvent, if not negligible, usually is balanced out by filling the comparison cell with the solvent. In physiologic fluids there are, in general, other substances in solution (or in colloidal suspension) besides the substance under investigation. All such substances absorb radiation; and since in many cases the absorption is not negligible, it is best, if possible, to balance it out by using as comparison fluid the identical physiological fluid, similarly diluted, with only the substance removed of which the transmission is to be measured.* If the substance cannot

*We usually neglect the error due to absorption in that part of the fluid which, in the comparison cell, occupies the space occupied in the other cell by the substance under investigation. In most cases the error is small.

be removed without altering the physical or chemical properties of the fluid, some fluid, such as distilled water, having negligible absorption, may be used as comparison substance. Correction must then be made for any appreciable absorption due to each of the other substances in the physiological fluid. The concentration of each substance must be found by some independent method and the corresponding transmission at each wave length computed by means of Equation (1). The transmission of the substance under investigation may then be found at any given wave length by dividing the observed transmission by the product of the transmissions of the other substances. In investigating bile pigment we have used this method in correcting for the absorption due to traces of oxyhemoglobin.

APPARATUS AND EXPERIMENTAL METHOD

The spectrophotometric observations were made by means of a quartz spectrograph and Hilger rotating sector photometer, with an under-water spark between tungsten terminals as source of radiation. These instruments were assembled and used in the usual manner, following essentially the method first described by Howe.⁹ The electrical circuits, quartz cells and container for the under-water spark have been described elsewhere.⁷

While the quartz spectrograph is to be preferred in most investigations because of its high dependability, our discussion of principles and methods will be understood to be applicable to the spectrophotometric investigation of bilirubin regardless of the kind of apparatus employed in finding the spectral transmission or absorption.

INTERFERENCE OF OXYHEMOGLOBIN WITH SPECTROPHOTOMETRIC OBSERVATIONS ON BILIRUBIN

It was found by spectroscopic examination that the majority of blood serums, however carefully prepared, contain traces of hemoglobin in the form of oxyhemoglobin, sufficient in amount to affect the absorption spectrum appreciably, even though the unaided eye may be able to detect little or none of the characteristic red color. No method is known whereby bilirubin alone can be removed from blood serum with the assurance that the serum will remain unchanged chemically or physically. This fact precludes the possibility of balancing out the absorption due to oxyhemoglobin (and other substances) by using the bilirubin-free serum as comparison fluid. Therefore in spectrophotometric measurements on bilirubin, corrections must be made for the radiation absorbed by oxyhemoglobin. The importance of this has been pointed out by Mann, Sheard, Bollman and Baldes¹⁴ in connection with visual spectrophotometric observations to determine the site of formation of bilirubin. Oxyhemoglobin has a very strong absorption band at the short-wave end of the visible spectrum, in the region covered by the most prominent and characteristic absorption band of bilirubin. The maximal optical density in the latter band is roughly twelve times as great as in the former. But we have found that the concentration of oxyhemoglobin in a serum which appears to the unaided eye to be free from red color actually may be much greater than the concentration of bilirubin; so that

the absorption in the oxyhemoglobin may be comparable to that in the bilirubin, in spite of the greater power of absorption of the latter.

To test the visibility of traces of oxyhemoglobin, various concentrations in water were prepared and the color noted when viewed against an illuminated white background. Thicknesses of solution of 1.5 and 9.0 cm. were examined, making direct comparisons with pure water. Data for the higher dilutions are given in Table I. Visual detection of oxyhemoglobin in blood serum is much

TABLE I
VISUAL APPEARANCE OF AQUEOUS SOLUTIONS OF OXYHEMOGLOBIN

HEMOGLOBIN, CONCENTRATION IN MG. PER C.C.	COLOR, VISUALLY OBSERVED THROUGH 1.5 CM. DEPTH	COLOR, VISUALLY OBSERVED THROUGH 9.0 CM. DEPTH
0.036	Not detectable, except when compared with pure water	Very faint pink, but noticeable
0.024	Not easily detected, even when compared with pure water	Hardly detectable, except when compared with pure water
0.007	Not detectable	Not detectable.

more difficult than in water, since the color of the serum tends to mask that of the oxyhemoglobin. We have found by spectroscopic and spectrophotometric measurements that amounts of from 0.05 to 0.10 mg. per c.c. frequently escaped detection by the unaided eye; while in one case a serum containing approximately 0.2 mg. of hemoglobin per c.c., or about 100 times the normal bilirubin content, appeared free from hemoglobin, the color being masked by that due to a high concentration of bilirubin. These concentrations of hemoglobin are easily high enough to modify the absorption spectrum greatly.

These data show clearly that in spectrophotometric studies of bilirubin in blood serum the possibility of errors caused by traces of oxyhemoglobin cannot be ignored, even in serums which appear free from red color. Corrections must be made for the effects of the oxyhemoglobin unless these effects can be shown to be negligible.

DETERMINATION OF CONCENTRATION OF TRACES OF OXYHEMOGLOBIN

The concentration of hemoglobin in traces of oxyhemoglobin in the serum was measured with a Keuffel and Esser spectrophotometer ("color analyzer") by the method described by the authors.⁶ This method, while accurate to 1 or 2 per cent for the concentrations of hemoglobin usually found in blood, is much less accurate for very low concentrations. But the accuracy is sufficient to permit of fairly reliable corrections for absorption by traces of oxyhemoglobin.

Another method, of about equal reliability for very low concentrations of hemoglobin, was used on some of the serums. The serum was diluted a known amount, shaken with air, and examined in a glass cell of adjustable thickness placed in front of the slit of a spectrometer. With light from an incandescent lamp (always the same lamp and voltage) passing through the cell, the thickness of serum was reduced until the absorption band of oxyhemoglobin at wave length 577 $m\mu$ disappeared. From the thickness at disappearance of the band, the concentration of hemoglobin was found by comparison with values obtained for known concentrations.

ABSORPTION SPECTRUM OF BILIRUBIN

To determine concentrations of bilirubin spectrophotometrically, it is necessary to measure the transmission only at one suitable wave length for which the absorption ratio is known. But in order to identify or otherwise investigate the pigment, one usually must determine the curve which represents the absorption spectrum. This may be represented by plotting absorptions, extinction coefficients or absorption ratios. Or transmissions may be plotted, since the values of transmission and of absorption are complementary. We shall plot transmissions.

So far as possible we shall reserve for a separate paper the discussion of the absorption spectra we have determined for various samples of bilirubin.

Fig. 1.—Spectrum of blood serum of jaundiced human being. For wave lengths longer than about 340 $m\mu$, the spectrum is typical of serum bilirubin. Concentration of bilirubin, 18.6 mg. per 100 c.c. Serum undiluted. Thickness, 0.128 mm.

However, to illustrate the general characteristics of the spectrum, we show in Figs. 1 and 2 the curves obtained for blood serums from two jaundiced patients. Distilled water was used as comparison substance, since bilirubin-free serum was not available, for reasons already stated. Hence the curves must show the absorption due not only to bilirubin but also to other substances in the serum. However, at wave lengths longer than 330 or 340 $m\mu$ no substance ordinarily present in serum, excepting hemoglobin or its compounds, is at all comparable to bilirubin in its power to absorb radiation. Therefore above 330 or 340 $m\mu$ the curves represent the absorption spectrum of bilirubin fairly closely, particularly in Fig. 1, where the concentration is very high. In Fig. 2 correction was made for the absorption due to oxyhemoglobin (upper curve), the broken line curve representing the corrected bilirubin spectrum. The curve in Fig. 1 needed no correction, since no oxyhemoglobin appeared in the serum.

The prominent band with maximal absorption at $280\text{ m}\mu$ is not characteristic of bilirubin. This is shown by the curves we have obtained for various samples of serum, from which it appears that the absorption in this region is independent of the concentration of bilirubin. Lewis¹¹ found the same band in the spectra of pseudoglobulin, euglobulin and albumin, from which he concluded that its appearance in the spectrum of blood serum is due specifically to the serum proteins. Later Stenström and Reinhard^{21, 22} decided from spectrophotometric evidence that the tryptophane and tyrosine constituents of the protein molecule are responsible for this band.

The curves in Figs. 1 and 2 are alike in general shape but differ in minor details. For the most part the minor differences are not due to experimental

Fig. 2.—Spectrum of blood serum of jaundiced human being. For wave lengths longer than about $340\text{ m}\mu$, the general shape of the curve (broken line) is typical of serum bilirubin. The lower curve represents observed transmissions. The upper curve is calculated, to represent the trace of oxyhemoglobin present in the serum and is used in obtaining the corrected curve (broken line). Bilirubin concentration, $4.3\text{ mg. per } 100\text{ c.c.}$ Serum undiluted. Thickness, above $298\text{ m}\mu$, 0.772 mm.

errors. The prominent feature of both curves, definitely characteristic of bilirubin, is the broad absorption band extending from the green region of the visible spectrum to the neighborhood of wave length $360\text{ m}\mu$ in the ultraviolet. The wave length of maximal absorption seems to vary somewhat. It is difficult to locate accurately, since the absorption band is very broad and rather "flat" at its lower end. In Figs. 1 and 2 maximal absorption is approximately at wave lengths 445 and $460\text{ m}\mu$, respectively. Practically all our curves for bilirubin in human blood serum gave evidence of maximal absorption at some wave length between these two values, the average being about $453\text{ m}\mu$. Rahier¹⁵ located it at $435\text{ m}\mu$ but did not state whether his observations were made on serum bilirubin or on solutions of purified bilirubin. We have found an aver-

age value of 432 $m\mu$ for purified bilirubin dissolved in 0.02 N sodium hydroxide, this value being the average of nine determinations.

ABSORPTION SPECTRUM OF OXYHEMOGLOBIN

The absorption spectrum of oxyhemoglobin, Fig. 3, was obtained from samples of blood from three normal men. Clotting was prevented by adding a little dry ammonium oxalate. The hemoglobin content was measured by the spectrophotometric method of the authors⁶ and was found to be normal in each case. Part of each sample of blood was centrifuged and the plasma used as fluid for comparison. The whole blood and plasma were diluted equally with 0.1 per cent sodium carbonate solution. After dilution the concentration of hemoglobin was 1.22 mg. per c.c. This solution was shaken with air to convert the

Fig. 3.—Spectrum of oxyhemoglobin normally present in human blood serum, computed for an assumed transmission of 30 per cent at wave length 427 $m\mu$.

hemoglobin into oxyhemoglobin. A layer 0.772 mm. thick was examined in each case.

Since the diluted blood was not centrifuged, the absorption represented in Fig. 3 includes that due to the stroma of the hemolyzed cells. The absorption by these cell bodies is small compared to that of the oxyhemoglobin, however. The following facts justify this statement: (1) Curves obtained by Strub²³ show this to be the case in the spectral range between wave lengths 450 and 660 $m\mu$. (2) In direct spectrophotometric comparisons of blood serums we have obtained several curves representing the spectrum of oxyhemoglobin alone. These agree closely with the curve in Fig. 3, from wave length 320 or 340 to 580 $m\mu$.

The curves from the three blood samples were exactly alike in general shape. Corresponding transmissions differed by less than the experimental

errors of measurement, over a major part of the spectral range represented. Positions of maxima and minima, 9 in all, agreed on the average to within 0.7 $m\mu$.

To calculate the curve of Fig. 3, a wave length in the principal absorption band was first chosen, at which wave length, 427 $m\mu$, all three curves indicated the same transmission. The optical densities ($-\log_{10} T$) at a considerable number of other wave lengths were each divided by the density at 427 $m\mu$ and at each wave length the average value of the three density ratios was used in calculating the transmission, arbitrarily assuming a value of 30 per cent at 427 $m\mu$. This procedure is based on the fact, previously stated, that for any two

Fig. 4.—Spectrum of oxygenated solution of purified hemoglobin dissolved in water containing a little ammonium hydroxide. Concentration of hemoglobin, 0.00121 gm. per c.c. Thickness, 0.772 mm. The α - and β -bands, at 577 and 542 $m\mu$, respectively, were visually observed but are not shown here because of their faintness and the uncertainty in measuring transmissions near 100 per cent in this spectral region.

wave lengths the ratio of optical densities is a constant independent of concentration and thickness. Some of the average density ratios are shown in Table II.

For comparison with Fig. 3 we show in Fig. 4 the transmission curve for a solution of purified hemoglobin in water containing a little ammonium hydroxide (1 part of fairly concentrated ammonium hydroxide to 125 parts of water). The hemoglobin was prepared by the method of Welker and Williamson. In the solution the concentration of hemoglobin was 1.21 mg. per c.c. The solution was examined spectrophotometrically within thirty minutes after preparation and was not exposed to radiation which might cause it to "fade." The solution was shaken with air just before examination. We are not prepared to say whether the resulting compound of hemoglobin was oxyhemoglobin or a salt of hemoglobin. However, we note that when sodium hydroxide was substituted for the ammonium hydroxide, visual spectroscopic examination revealed a broad

absorption band centered at about wave length 620 m μ , in addition to the usual α - and β -bands at 577 and 542 m μ , shown by both solutions. The α - and β -bands were less distinct than in the solution with ammonium hydroxide. (In Fig. 4 these bands are not indicated, for reasons noted under the figure.) These differences show that the nature of the compound of hemoglobin obtained in such a solution depends on the kind of alkali which is added.

It is seen by comparing Figs. 3 and 4 that although the two spectra are generally similar, the spectrum in Fig. 4 differs from that in Fig. 3 in the following particulars: (1) considerably greater absorption in the spectral region lying approximately between wave lengths 340 and 395 m μ ; (2) very much less absorption in the principal part of the most prominent absorption band, roughly from 395 to 440 m μ ; (3) less absorption in the region of the α - and β -bands, 577 and 542 m μ . These differences could not be due to the stroma in the serum, since these bodies would increase rather than decrease the absorption shown in Fig. 3, which action could not cause the first difference, and since the stroma does not absorb specifically in the spectral regions of the three bands mentioned in the statement of the second and third differences. A reliable quantitative comparison of the two curves may be made by comparing corresponding ratios of optical density. Some such ratios with respect to the density at wave length 460 m μ are shown in Table III. Wave lengths of maximal and minimal absorption up to 510 m μ are represented, with some inter-

mediate values. While at each wave length the magnitude and algebraic sign of the difference shown in the last column are dependent on the choice of wave length at which the optical density is taken as reference, the great range in magnitudes and the wide departures from zero show without ambiguity that the two spectra cannot belong to identical substances, although the substances evidently are rather closely related chemically. This would be true also if sodium hydroxide were substituted for the ammonium hydroxide in preparing

TABLE III

the compound of hemoglobin, as is shown by the nature of the resulting modifications observed in the absorption spectrum. Therefore we conclude that the oxyhemoglobin normally present in blood is not identical with the compound formed by oxygenating a solution of purified hemoglobin in water containing a small amount of ammonium hydroxide or of sodium hydroxide.

The curves in both Figs. 3 and 4 gave evidence of a very strong absorption band, less strong in Fig. 4, with maximal absorption at 418 $m\mu$. Two other conspicuous bands appear in the ultraviolet, with maximal absorption located at or very near wave lengths 271 and 343 $m\mu$ in Fig. 3 but much less definitely indicated as to position in Fig. 4. In Fig. 4 the separation of the bands at 418 and at or near 343 $m\mu$ is masked by the absorption in the region between them. Both curves show a cut-off at about 230 $m\mu$.

Few accurate data have been published on the absorption spectrum of oxyhemoglobin in the ultraviolet and shorter wave lengths of the visible spectrum. Kayser¹⁰ refers to a number of observations made by various investigators between 1878 and 1904, but many of the data secured are unreliable or are expressed only in approximate figures. Strub²³ has published absorption curves and data for the visible region above 450 $m\mu$. Suhrmann and Kollath²⁴ show absorption curves for solutions of blood, in general shape closely similar to the curve in Fig. 3 and with the positions of the absorption bands approximately the same. But only eight values are plotted in the entire spectral range between 315 and 580 $m\mu$, so that the shape of the curve and the positions of maxima

and minima as shown can be considered only as rough approximations. Hicks and Holden⁶ have published values of the wave lengths at which maximal and minimal absorption occur in solutions of oxyhemoglobin in the ultraviolet and violet spectrum. The oxyhemoglobin was prepared by the method of Adair. In the principal band, maximal absorption was observed at 411.5 $m\mu$. Berg and Schwarzaeher¹ located maximal absorption at 413.7 $m\mu$. Details of their experimental work are not given.

As shown in Fig. 3, we find that in the case of oxyhemoglobin occurring normally in human blood serum, maximal absorption in the principal absorption band occurs at 418 $m\mu$. This location is clearly indicated in a considerable number of other spectra which we have charted. Early observers, for the most part employing less accurate methods of measurement, usually assigned some value between 408 and 415 $m\mu$. In treatises on physiologic chemistry and in other recent writings, one of these earlier values usually is quoted, apparently without verification. In the absorption curves obtained by Suhrmann and Kollath, maximal absorption is indicated at about 408 $m\mu$. But the curves are only rough approximations, for reasons already stated. The few points which are plotted fall more logically on a curve showing maximal absorption at 415 or 420 $m\mu$. In the measurements by Hicks and Holden, who found maximal absorption at 411.5 $m\mu$, it is to be remembered that their results are for solutions of purified oxyhemoglobin. In view of our demonstration of the lack of identity between oxyhemoglobin normally present in blood and the compound of hemoglobin formed by oxygenating a solution of purified hemoglobin in water containing a small amount of ammonium hydroxide or sodium hydroxide, it cannot be assumed a priori that the oxyhemoglobin examined by Hicks and Holden has an absorption spectrum identical with that of oxyhemoglobin occurring normally in blood.

The average value of the absorption ratio of oxyhemoglobin at wave length 418 $m\mu$, as computed from the three curves from which Fig. 3 was calculated, is 0.000,136 gm. per sq. cm., where the concentration is in gm. per c.c. and the thickness in cm. At 427 $m\mu$ the value is 0.000,181. Using these values and the density ratios in Table II to calculate the absorption ratio at 542 $m\mu$, the wave length of maximal absorption in the β -band, the value comes out 0.00133, not in close agreement with the value 0.00110 previously found by the authors.⁶ But 0.00133 is much less reliable, being based on curves showing transmissions of 82, 85, and 88 per cent, respectively, at wave length 542. At high transmissions (T) the optical densities ($-\log_{10} T$) are small and vary rapidly with changes in T. Therefore the accuracy of the determined values of optical density and corresponding density ratios is affected to a disproportionately large degree by errors in T, the effect increasing as T approaches 100 per cent. The curve showing T = 82 per cent at 542 $m\mu$ gives an absorption ratio of 0.00107, in good agreement with the value found previously.

METHOD OF CORRECTING FOR ABSORPTION BY OXYHEMOGLOBIN IN DETERMINING THE ABSORPTION SPECTRUM OR CONCENTRATION OF BILIRUBIN

We have presented data which clearly show the necessity of making corrections for the absorption due to traces of oxyhemoglobin when investigating serum

bilirubin spectrophotometrically. If only the concentration of the bilirubin is to be determined, it is only necessary to find the transmission of the oxyhemoglobin at one wave length, namely, that wave length at which the transmission of the bilirubin is used in calculating its concentration. But if the nature of the investigation makes it necessary to map the absorption spectrum of the bilirubin, the transmission of the oxyhemoglobin must be determined at a sufficient number of wave lengths to make it possible to correct the observed transmission spectrum throughout its length. In either case the transmission of the oxyhemoglobin at any wave length shorter than about 520 or 530 $m\mu$ must be calculated from its concentration, since the bilirubin interferes with direct measurement of the oxyhemoglobin transmission. The two methods of estimating traces of oxyhemoglobin have been presented and discussed. The procedure to be followed in making the corrections will be made clear by the following illustration:

In Fig. 2, the portion of the curve labeled "serum" lying between wave lengths 340 and 580 $m\mu$ is the typical uncorrected curve for serum which contains an abnormally high concentration of bilirubin. The hemoglobin concentration (C) was estimated to be 0.000,17 gm. per c.c., an amount too small to be detected by the unaided eye. The thickness (L) of serum was 0.0772 cm. The absorption ratio (A) of oxyhemoglobin at 427 $m\mu$ (the choice of wave length is arbitrary, providing we use the proper absorption ratio) is 0.000,181 gm. per sq. cm. Therefore at this wave length the transmission T_{427} is found by substitution in Equation (1), which gives

$$0.000,17 = - \frac{0.000,181}{0.0772} \log_{10} T_{427},$$

from which $T_{427} = 0.846$ or 84.6 per cent. The transmissions at other wave lengths are found from this value by the use of Table II. For example, at 380 $m\mu$ we have, from the table,

$$\frac{-\log T_{380}}{-\log T_{427}} = 0.315.$$

Since $T_{427} = 0.846$, this gives $T_{380} = 0.949$ or 94.9 per cent. Plotting this value and others similarly found, the oxyhemoglobin curve shown in the figure is drawn. To correct the observed spectrum (curve marked "serum"), the transmission at each of a number of different wave lengths is divided by the corresponding transmission shown by the oxyhemoglobin curve. For example, at 430 $m\mu$ the respective transmissions are 50.3 and 87.1 per cent, therefore the corrected value is 50.3/87.1 or 57.7 per cent. This value and others similarly determined are plotted to obtain the dotted curve labeled "serum minus oxyhemoglobin," which represents the corrected bilirubin spectrum between wave lengths 340 and 580 $m\mu$.

In case the oxyhemoglobin transmission is first calculated for some wave length, λ_1 , other than 427 $m\mu$, the density ratios in Table II cannot be used. Instead, new values are found by dividing each tabulated value by the value given for λ_1 . For example, if λ_1 is 418 $m\mu$, the density ratio with respect to it will be, at 400 $m\mu$, 0.664/1.33 or 0.499; at 450 $m\mu$ it will be 0.194/1.33 or 0.146; and so on.

If it is desired only to find the concentration of the bilirubin, it is unnecessary to determine the entire oxyhemoglobin curve. Only one value of transmission is needed. For example, if the transmission of the serum is determined at wave length 410, it is necessary to know the transmission of the oxyhemoglobin only at that wave length. The method of finding it is illustrated above. The correction is made by dividing the observed transmission of the serum at 410 $m\mu$ by the corresponding transmission of the oxyhemoglobin. The corrected value is used in calculating the bilirubin concentration by means of Equation (1).

Such corrections may seem somewhat laborious. But if serum bilirubin is to be studied spectrophotometrically, either the corrections must be made or it must be shown that oxyhemoglobin is not present in amount sufficient to alter the spectrum significantly. So far as oxyhemoglobin in serum is concerned, the unaided eye is incapable of deciding whether the serum is spectrally "clear" or not.

DETERMINATION OF CONCENTRATION OF BILIRUBIN

The concentration of bilirubin is found by substituting in Equation (1) the values of A, L, and T. It is best to determine the transmission T at some wave length in the most prominent absorption band, preferably at or near the wave length at which maximal absorption occurs. In the case of bilirubin in human blood serum, we have found this wave length to be approximately 453 $m\mu$. The exact value is immaterial, since the absorption band is broad and the transmission near the minimum varies but little over a considerable spectral range (Figs. 1 and 2). Minimal transmission in the narrower oxyhemoglobin band is at 418 $m\mu$. Therefore the error due to absorption by traces of oxyhemoglobin may be largely avoided by measuring the transmission at 450 or 460 $m\mu$, since at these wave lengths the absorption by oxyhemoglobin is very much less than at 418 $m\mu$ (Fig. 3).

In Table IV are shown the values of the absorption ratios of bilirubin at wave lengths 450 and 460 $m\mu$, calculated from transmission curves obtained in our investigations of the two types of bilirubin in human blood serum and in our observations on the development of obstructive jaundice in the dog. All the serums were undiluted when examined, except the second, fifth, and sixth, which were diluted to one-third the concentration shown in the table by adding 0.1 per cent sodium carbonate solution.

The serums were prepared as follows: The blood was carefully drawn and placed in an ice box until clotted, after which the clot was loosened and the serum obtained by centrifuging. The serum was returned at once to the ice box or put in a Dewar flask containing ice at 0° C., where it was left until its spectrophotometric examination, which was made within a few hours. Since the serum was kept in the dark and at 0° or a little above, "fading" probably was inappreciable.

In averaging the values of the absorption ratios (A, Table IV), each was assigned a weight proportional to the reciprocal of the error in A resulting from an error of 1 per cent transmission in determining the transmission. Such

error in A becomes progressively larger as the transmission approaches 0 per cent or 100 per cent and is smallest in the range from about 20 per cent to 60 per cent.

The individual values of A in Table IV admittedly vary too much to warrant regarding the averages as highly accurate. To a small extent the variations are due to inaccuracy of the spectrophotometric determinations. But careful consideration has led us to conclude that the variations are due mostly to errors in the values of bilirubin concentration C as determined by the van den Bergh method. In spite of the large average deviations, the average values of A obtained from blood serum of man and of dog are in close agreement. The differences (3.5 and 1.8 per cent) are too small to be considered as other than experimental. The values for the two kinds of serum probably are identical. Also, for each serum the average values at wave lengths 450 and 460 $m\mu$ are very nearly equal. For either wave length and for the serum either of man or of dog we may consider 11.3×10^{-6} or 0.000,011,3 gm. per sq. cm. as the correct value of the absorption ratio of bilirubin. This agrees closely with the value 11.4×10^{-6} found by Cutten, Emerson and Woodruff² for bilirubin dissolved in chloroform, at wave length 450 $m\mu$.

It is recommended that in determining the concentration of bilirubin in blood serum the transmission be observed at wave length 450 or 460 $m\mu$. The latter is preferable, since at this wave length oxyhemoglobin absorbs a little less radiation than at 450 $m\mu$. The absorption ratio for oxyhemoglobin at 460 $m\mu$, calculated from Table II and the value 0.000,136 at 418 $m\mu$, is 0.001,20 gm. per sq. cm.

TABLE IV

VALUES OF THE ABSORPTION RATIOS (A_{450} AND A_{460}) OF BILIRUBIN IN BLOOD SERUM, AT WAVE LENGTHS 450 AND 460 $m\mu$. C IS THE CONCENTRATION OF BILIRUBIN AS DETERMINED BY THE VAN DEN BERGH METHOD

Weighted average of all values of $A_{460} = 11.3 \times 10^{-6}$ gm. per cm. ²					

SUMMARY AND CONCLUSIONS

The ultraviolet and visible absorption spectrum of bilirubin in blood serum was investigated by means of a quartz spectrograph and rotating sector photometer, with an under-water spark as source of radiation. Data were obtained

on the visibility of small amounts of oxyhemoglobin in water and in blood serum, and on the effects of traces of this pigment in spectrophotometric investigations of the components of serum, particularly bilirubin. Characteristic spectra of serum bilirubin, of serum oxyhemoglobin and of an oxygenated solution of purified hemoglobin in alkalized water are shown and discussed. Some constants of the absorption spectra of serum oxyhemoglobin and of serum bilirubin are evaluated. A method of calculating the spectrum of a small amount of oxyhemoglobin in serum and of correcting the observed spectrum is described. The principal conclusions are as follows:

1. In blood serum, traces of oxyhemoglobin not detectable by the unaided eye may absorb considerable amounts of radiation, modifying the absorption spectrum greatly.
2. In spectrophotometric investigations of bilirubin in blood serum, corrections must be made for absorption of radiation by traces of oxyhemoglobin, even in serums which appear "clear," unless it can be shown that such absorption is negligible.
3. In correcting the absorption spectrum of blood serum or of other body fluid for the absorption due to oxyhemoglobin, it is necessary to determine the concentration of oxyhemoglobin and then calculate its transmission (a) at various wave lengths, in case the nature of the spectrum is in question; or (b) at one particular wave length only, in case only the bilirubin concentration is required.
4. The most prominent absorption band of serum bilirubin is very broad. In human serum, minimal transmission in this band occurs at or near $453\text{ m}\mu$. Minimal transmission in the most prominent absorption band of oxyhemoglobin in serum is at $418\text{ m}\mu$.
5. The oxyhemoglobin normally present in blood is not identical with the compound formed by oxygenating a solution of purified hemoglobin in water containing a small amount of ammonium hydroxide or of sodium hydroxide.
6. Serum oxyhemoglobin has the following absorption ratios, in gm. per sq. cm.: at $418\text{ m}\mu$, 13.6×10^{-6} ; at $427\text{ m}\mu$, 18.1×10^{-6} ; at $460\text{ m}\mu$, 12.0×10^{-6} . The absorption ratios of serum bilirubin at 450 and $460\text{ m}\mu$ are very nearly equal, both having approximately the value 11.3×10^{-6} gm. per sq. cm., both in the serum of man and of dog.
7. It is recommended that in spectrophotometric determinations of the concentration of bilirubin in blood serum, the transmission be observed at wave length $460\text{ m}\mu$.

A COMPARISON OF BLOOD SUGAR CURVES WHEN GLUCOSE IS GIVEN ORALLY AND INTRADUODENALLY*

ELIZABETH J. MAGERS, PH.D., POUGHKEEPSIE, N. Y.

THE glucose tolerance test is a common clinical diagnostic aid, but its value depends upon a knowledge of the various processes concerned in the response and upon a careful control of the factors which influence its interpretation. These factors include the previous period of fasting, the source of the blood used and the amount of exercise taken during the test. Since the absorption of glucose by the stomach is negligible¹ it seems possible that the emptying rate of the stomach might also influence the curve obtained.

*From the Laboratory of Pathological Chemistry, University Hospitals, State University of Iowa, Iowa City, and the Department of Physiology, Vassar College. Received for publication, April 25, 1933.

In support of this hypothesis John² observed that nausea produced "peculiar dips" in certain blood sugar curves which he interpreted to mean that absorption was delayed or stopped for a short time. Beeler, Bryan, Cathart and Fitz,³ however, noted that after the ingestion of 100 gm. of glucose by subjects without evident gastric disease, from 26 to 68 per cent of the glucose was still in the stomach at the end of an hour. In the one case in which blood

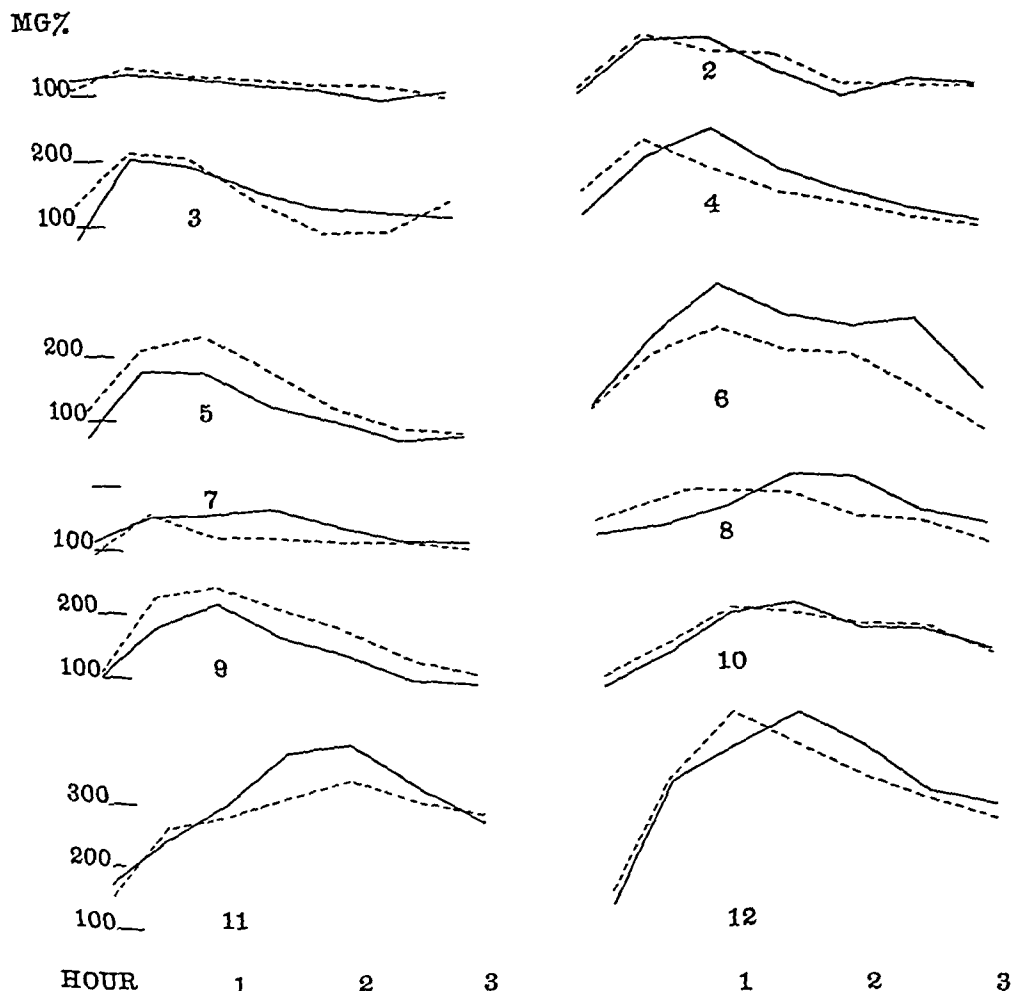

Chart 1.—Blood sugar curves when glucose is given orally and intraduodenally.
—Oral curve. ---- Duodenal curves.

sugar figures were reported, the curve reached a peak in thirty-five minutes and had nearly returned to the fasting level in one hour. The stomach at this time contained 27 gm. of glucose, an amount which if given to a fasting person would increase the blood sugar. This may be explained by the work of Cori⁴ who has shown that glucose is absorbed from the intestine at a constant rate which within wide limitations is independent of the concentration; and that even after a moderate carbohydrate meal glucose absorption is at a

maximum. He states:⁵ "No indication was obtained, as in the case of alcohol, that emptying of the stomach is a limiting factor (in absorption) though perhaps more work is required to settle this problem definitely."

To what extent then does the emptying of the stomach influence the interpretation of the blood sugar curve? Earlier work on this question was done by Hale-White and Payne⁶ who reported an experiment on one subject to whom they gave glucose into the duodenum at various rates. When 50 gm. was given within eleven minutes, the blood sugar curve was almost identical with the one obtained when glucose was given by mouth. When the rate of administering the glucose was decreased so that the time required was one and five-tenths hours, it was found that the rise was almost identical with the other two curves, that the duration of hyperglycemia was greatly increased and that the descent was similar in all instances. They concluded from this case that the emptying rate of the stomach probably does not influence the initial rise of the blood sugar, but that it may change the period of hyperglycemia.

It was believed that the clinical significance of the emptying rate of the stomach could be more adequately ascertained by comparing blood sugar curves obtained when glucose was given directly into the duodenum with those obtained when glucose was given by mouth. For this study 12 subjects were chosen at random from the hospital wards. Two tests were made on each subject at an interval of not less than three days. The test when glucose was given by mouth was conducted as usual. After a fourteen-hour fast the subjects were given 50 gm. of glucose in a 15 per cent solution as that was the concentration found³ to pass most quickly from the stomach. The subjects drank the solution as rapidly as possible, the ingestion requiring less than a minute. Finger blood for sugar determination was obtained before the ingestion of the glucose and for each half hour thereafter for three hours. Blood sugar was determined by means of the Boyd-Gibson micromodification of the Folin-Wu method.⁷

For the duodenal tests a Rehfuß tube was given. It was considered that the bucket was in the duodenum when a bile-stained alkaline fluid was obtained by aspirating. The fasting blood sugar was not taken until after the tube was in the duodenum, so that if any change occurred in the blood sugar due to the swallowing of the tube it could be considered the fasting level. Warmed glucose solution of the same concentration as previously given by mouth was then given, the administration usually taking from three to five minutes. Blood samples were taken as before.

The data obtained are given in Table I and Chart 1. It is evident that the fasting level of the duodenal curves is slightly higher than the oral curves in 7 of the 12 cases. The height of the peak in the two types of curves shows no consistent relationship, the duodenal peaks are higher in 5 cases, lower in 4 cases and the same as the gastric curves in 3 cases. At the end of the three hours the blood sugar values of each pair of curves approximate each other very closely.

*The second series is the duodenal curve in each case.

It is apparent from the charted curves that the general shape of the two curves for each patient is quite similar. One curve may run consistently higher or lower than the other; when there is a tendency toward a plateau, it is evident in both curves.

SUMMARY

Blood sugar curves following the administration of 50 gm. of glucose by mouth and intraduodenally show no consistent difference.

It is concluded, therefore, that the emptying rate of the stomach ordinarily has little or no effect on the glucose tolerance test.

ELLIPTICAL RED BLOOD CELLS IN MAN*

A REPORT OF ELEVEN CASES

SARAH H. McCARTY, A.B., BIRMINGHAM, ALA.

IN HEALTH the erythrocytes of man exhibit such a remarkably constant shape that it is of considerable interest when the microscopist encounters an individual whose erythrocytes in a large proportion of their numbers appear not as the usual biconcave discs we are accustomed to see, but as flattened ellipsoids. This paper is a report of eleven such cases. Four of them were discovered in the routine microscopic examination of bloods from approximately 10,000 individuals. The other seven cases are relatives of three of these four patients.

HISTORICAL

During the past twenty-nine years this anomaly has been observed in more than sixty individuals. The first case was reported by Dresbach^{1, 2} in 1904. The subject was a young medical student who was apparently in good health at the time. The observation occasioned considerable scientific debate, since the young man died shortly thereafter of a rheumatic heart. One of Dresbach's contemporaries³ insisted that the poikilocytosis was the result of an obscure form of pernicious anemia or purpura, but Ewing, Erlich and other noted pathologists came to the conclusion that it was an anomaly having no relation to a primary blood dyscrasia, since the red cell count and hemoglobin values were "up to standard." Ewald in a personal communication to Dresbach stated that a similar observation had been made at Königsberg twenty or thirty years previously.

The second case was reported by Bishop⁴ in 1914. The patient was a white male, aged forty-one, who exhibited no evidences of an anemia. Bishop was able to examine blood from members of his patient's family and found the erythrocytes of a sister similarly deformed.

Three cases were reported in 1923, one by Sydenstricker⁵ and two, a mother and daughter, by Huck and Bigelow.⁶

In 1927 Lawrence⁷ reported a series of eight cases of elliptical and sickle-shaped red cells. Since none of his patients exhibited a high percentage of deformed cells (5 to 10 per cent is the most reported and this patient suffered from a marked anemia) and since he makes no distinction between sickle cells and elliptical cells, though he pictures both, these cases have not been included in the total figures of this series.

In 1928 eleven cases of elliptical erythrocytes were reported from Germany and Holland, 5 by van den Bergh,^{8, 10} 1 by Bernhardt,⁹ and 5 by

*From the Hillman Hospital Laboratory.
Received for publication, April 20, 1933.

Günther.¹¹ Van den Bergh examined the family of his first patient, and found the father and two sisters similarly affected. These 3 individuals were healthy and had no anemia.

In 1929 Hunter and Adams¹² definitely established the familial nature of the phenomenon by observing the peculiarity in 3 generations of a family of Dutch extraction who had emigrated to the Northwest.

In 1931 Lawrence¹³ described 5 cases; 2 of the patients were the child and grandchild of one of his hospitalized patients. Later in the same year van den Bergh and Rehorst¹⁴ investigated the antecedents of the family K1..., the American branch of which had been described by Hunter and Adams. They found 7 other individuals similarly affected. Many of the relatives refused to have their blood examined or it is probable that the K1...s would have swollen the statistics on elliptical cells still further. In July, 1931, Roth and Jung¹⁵ described another case in a young white woman whose blood had been observed over a period of nine years with no appreciable change in the percentage of cells exhibiting the deformity.

In February, 1932, Terry and his associates^{16, 17} described two cases with autopsy. In March, 1932, Cheney¹⁷ reported the largest series of cases, 14 in all, in 3 generations of a family of Italian extraction.

In the last twenty-nine years, then (excluding the observations of J. S. Lawrence in 1927), the anomaly has been observed in 57 individuals and in 17 family groups. In addition there are known to be 11 cases not yet reported in the literature. Sydenstricker has observed 6 cases in addition to the one he reported, Jaffe has observed 2, and van den Bergh reports 2, one seen by Dr. Pelger of Amsterdam and one by Dr. Vroorn-Hilder. I include also the case at Königsberg with which Ewald was familiar. Males and females have been about equally affected. It has been seen in the mulatto, the American negro and in whites of Dutch, German, Italian, Scotch, and Hebrew extraction. The youngest individual known to have the peculiarity was aged nine months (see below) and the oldest was aged eighty-four (Günther's case¹¹).

CASE REPORTS

On only 3 of our cases was it possible to do detailed work. These patients remained in the hospital for some time and have been observed from time to time ever since. In the case of relatives showing the elliptical anomaly, it was practicable to make only microscopic blood examinations.

CASE 1.—B. T., a negress, aged twenty-five years, was admitted to the Hillman Hospital with typhoid fever. The Widal reaction was strongly positive, the leucocytes numbered 7,150. In making the differential blood count it was noted that 90 per cent of the red blood cells were peculiarly deformed, being about twice as long as they were broad. At this time we were investigating the incidence of meniscoeytosis among our hospital patients, and we prepared wet preparations of this blood in the usual manner. The striking elliptical deformity was present in these wet preparations also, but no "sickling" occurred. Repeated examinations of smears and cells collected in various fluids, Hayem's solution, Locke's solution, physiologic saline, citrate, and oxalate, always revealed the same abnormality. Blood has been collected from this woman from time to time during the last eight years. The hemoglobin values have ranged from 74 to 68 per cent (Sahli), the erythrocyte count from 4,630,000 to

in the long axis of the cell. These cells resembled more closely than any others in this series the cells seen in the blood smear of a camel.

Hemoglobin values have ranged from 56 to 84 per cent (Sahli) in samples of blood taken at various times during the last five years. The erythrocyte counts have varied from

Fig. 2.—Stained film of blood of F. M.

Fig. 3.—Wet preparation of blood of F. M.

Fig. 4.—Wet preparation of blood of E. M., son of F. M. The percentage of elliptical cells is much less than in the mother's blood.

2,870,000 to 4,030,000 per c.mm. with a color index always of 1.1. The volume index was 1.04. It will be seen that although these cells are unusually long, their measurements for breadth and thickness are so diminished that they have very nearly a normal volume. "Fragility" test: initial hemolysis at 0.40 per cent NaCl, complete hemolysis in 0.32 per cent NaCl. Reticulocytes 0.3 per cent. Icteric index 9.

3,200,000 per c.mm. All hemoglobin values have been checked with the Van Slyke apparatus and counts have been made with U. S. Bureau of Standards pipettes. Except for a brief period when the patient was recovering from an anemia due to a severe menorrhagia, the color index has always been slightly greater than 1. In spite of this the cells in the smear appeared achromic. In examining wet preparations these pale-staining central areas appeared to represent biconcavities. In addition to the definitely elliptical cells there were many poikilocytes, sausage-shaped, bifid and tailed forms. The elliptical cells varied considerably in their dimensions. Micrometer measurements made on 1,000 cells in wet preparations gave average diameters of 10 by 4.5 by 2.7 micra. The thickness of the cell was hard to calculate, owing to the difficulty with which rouleaux were formed. Instead of stacking in rouleaux, the cells tended to group themselves in chains with the ends of the cells overlapping, similar to the phenomenon observed in camels' cells by Ponder.²⁵ Various methods for more accurate measurements were attempted, notably the Price-Jones method,^{23, 26} but this proved too elaborate for routine use, and it was found difficult to measure the fresh cells accurately even with the micrometer, owing to the movement of the cells in the suspending fluid. Following Haden's suggestion¹⁰ and working somewhat along the lines adopted by Emmons,²⁰ it occurred to us that the volume index might offer a good check on the size of the cells, since this would give us measurements of fresh cells in three dimensions. The volume index of this woman's blood was 1.23, as compared with a normal of 0.96.

Fig. 1.—Stained film of blood of B. T. Tailed and bifid poikilocytes are seen.

The percentage of deformed cells was 91.1 in smears and 91.0 in wet preparations. These figures are based on counts of the number of poikilocytes occurring in 1,000 cells suspended in Hayem's fluid, and 1,000 fixed cells. The reticulocyte count was 0.2 per cent, the icteric index 3.9. Initial hemolysis occurred in 0.44 per cent NaCl, and was complete in 0.30 per cent.

Two sisters and a niece aged nine months, exhibited the anomaly. One sister had 17 per cent of deformed cells, the other 27 per cent. The baby showed 26.9 per cent of the erythrocytes to be elliptical. A brother and two first cousins showed no alteration in the shape of their red cells.

CASE 2.—F. M., a negress aged twenty-six years, was admitted to the gynecologic service in March, 1928, and salpingectomy was performed. Microscopic examination of the blood showed elliptical erythrocytes occurring in the following percentages:

96.01 per cent in Hayem's solution
78.4 per cent in fixed smears

The elliptical cells were much more uniform in measurement than in the case of B. T. The largest cell measured was 11.5 by 5.5 micra, the smallest 8.6 by 4.8 micra. Average measurements for 1,000 cells in wet preparations were 9.6 by 5.4 by 1.8 micra. In some cells two pale-staining areas taken to represent biconcavities were seen one below the other placed

in the long axis of the cell. These cells resembled more closely than any others in this series the cells seen in the blood smear of a camel.

Hemoglobin values have ranged from 56 to 84 per cent (Sahli) in samples of blood taken at various times during the last five years. The erythrocyte counts have varied from

Fig. 2.—Stained film of blood of F. M.

Fig. 3.—Wet preparation of blood of F. M.

Fig. 4.—Wet preparation of blood of E. M., son of F. M. The percentage of elliptical cells is much less than in the mother's blood.

2,870,000 to 4,030,000 per c.mm. with a color index always of 1.1. The volume index was 1.04. It will be seen that although these cells are unusually long, their measurements for breadth and thickness are so diminished that they have very nearly a normal volume. "Fragility" test: initial hemolysis at 0.40 per cent NaCl, complete hemolysis in 0.32 per cent NaCl. Reticulocytes 0.3 per cent. Icteric index 9.

The family of this woman proved rather difficult to examine, but the patient's three sons consented to have samples of blood withdrawn. One of them aged six years showed 17.7 per cent elliptical cells in smears, and 20 per cent in suspensions of Hayem's fluid. The other two showed no abnormalities.

CASE 3.—P. T., a negro male, aged fifty-four years, was admitted to the medical ward with lobar pneumonia in June, 1928. When the differential smear was counted a large percentage of elliptical cells were noted and the technician returned to the ward for further specimens. In the meantime, the patient had died. His relatives refused permission for autopsy and also to have specimens of their blood examined. This case is recorded merely to complete the incidence of the anomaly in this series, since confirmatory examinations could not be made.

CASE 4.—E. Mc., a negro man, aged forty-eight years, was admitted to the medical service in March, 1930, with acute alcoholism; 48 per cent of his erythrocytes were of

Fig. 5.

Fig. 6.

Fig. 5.—Stained film of blood of patient E. Mc. A few "double biconcave" cells can be seen.
Fig. 6.—Wet preparation of blood of E. Mc.

elliptical outline when seen in Hayem's fluid, 40 per cent were elliptical in smears. His cells were the largest noted in our series, averaging 13.3 by 5.78 by 2.89 micra (micrometer measurements in wet preparations). The round cells had an average diameter of 8 mu. Hemoglobin values have varied from 78 to 74 per cent (Sahli) red counts from 4,160,000 to 4,030,000 with a color index of 0.9. The volume index was 1.5. This is a higher value than is the average even in pernicious anemia. The cells packed to 60 per cent of the whole blood volume, whereas normal cells pack to 48 per cent of the blood volume. The volume of the elliptical cells computed from actual measurements is 193.2 c. micra. This will give some idea of their enormous size. "Fragility" test: initial hemolysis at 0.40 per cent, complete hemolysis at 0.30 per cent NaCl, reticulocytes 0.3 per cent, and icteric index 6.9.

It was possible to examine the blood from three generations of this family. Two daughters aged twenty-four and twenty-seven years, showed 15.6 and 17 per cent elliptical cells in Hayem's fluid. A granddaughter aged three years showed 10.3 per cent elliptical

cells. In examining bloods showing less than 20 per cent of the erythrocytes to be elliptical, it is rather hard to recognize the anomaly and in routine examination we would probably pass them up at best with a remark of "moderate poikilocytosis."

INVESTIGATIONS TO DETERMINE THE NATURE OF THE ANOMALY

1. The first problem that presented itself was the necessity of differentiating the elliptical phenomenon from menisocytic anemia. The two kinds of deformity are in no way comparable. In the first place, sickle cells are rarely present in large numbers in blood smears, the percentage of deformed cells increasing materially when a drop of blood is placed under a thin cover slip and an interval of several hours allowed to elapse. The percentage of elliptical cells when examined in wet preparation after a lapse of several days remains the same. Again when a drop of blood from a "sickler" is placed between a slide and cover slip and fixed in formalin by the time fixation is complete, practically every cell is deformed. Cells from elliptical cell patients show no material change in size or shape after formalin fixation. Sickle cell anemia is a disease characterized by periods of exacerbation when blood destruction is very evident. There is urobilinuria, increase of bile pigments in the serum. Examination of urine from the three elliptical cell patients on whom it was possible to do extensive work showed no urobilin. While the icteric index of one of these patients (F. M.) was 9, well within the range of latent icterus, the quantitative van den Bergh reaction gave an amount of serum bilirubin too small to estimate colorimetrically. Again sickle cell cases show at periods remarkable activity of the hematopoietic system, as indicated by enormously increased reticulocyte counts. None of these cases showed any increase in reticulocytes, and it is of note that in the literature reticulocytes were increased only in those subjects who showed a concurrent anemia. Finally, none of the clinical evidences of sickle cell anemia were present. It seems conclusive to us, therefore, that this anomaly is in no way connected with sickle cell anemia, and its causal relationship to any other anemia, or to any disease, has never been definitely established.

Our next problem was a study of the external factors which might influence the shape of these elliptical cells. Many observers have noted that various physical forces, such as pressure on the cover slip, washing repeatedly in isotonic saline solution, and increase in temperature diminished the percentage of elliptical cells, or even caused them to disappear entirely. We have never observed any change in the shape of the elliptical cells due to any of these factors. Wet preparations sealed with paraffin and observed over a period of six weeks showed no evidence of "rounding up," either when kept at room temperature, in the ice box, or in the incubator. The only change in the incubator preparations was a more rapid hemolysis than in the preparations kept at lower temperatures. Cells washed six times in isotonic saline showed no increase in the percentage of round forms by actual counts.

We tried to determine the cause of the smaller number of ellipses occurring in the smears than in the wet preparations. We found this in all but one of our cases (B. T.). This has been found also by most observers, notable exceptions being Hunter and Adams¹² who found about 10 per cent less de-

formity under No. 0 cover slips, than in stained smears. Günther¹¹ has offered a rather ingenious explanation for this "rounding up" of ellipses when they are spread out, but to me it is not entirely conclusive. I have examined smears of camel's blood, kindly furnished me by Dr. Charles Noback of the New York Zoological Gardens. At the margins of these smears, and in areas where the cells are deformed by pressure from other cells, an occasional round cell is seen. Any one who routinely examines large numbers of blood smears has observed that there is frequently considerable variation in the shape and size of the cells in certain areas, even with the greatest care of glassware and the most constant technic.

The influence of chemical agents on the shape of the elliptical erythrocytes was studied as follows:

A. *Hemolytic Agents*.—Hypotonic sodium chloride, saponin and sodium taurocholate were used. With the saponin and sodium taurocholate we prepared dilutions in the strengths recommended by Yeager.²² Cells taken from the tubes where hemolysis was not complete were practically all ellipsoid. The elliptical cells appear, therefore, more resistant to hemolytic agents than the normally shaped cells. Cells examined from the hypotonic saline solutions appeared unusually large and full, the biconcavities have been smoothed out and the enveloping membrane appears tightly stretched over the swollen, turgid cell contents. This apparent swelling of the erythrocyte is always noted just before hemolysis in normal red blood cells.²⁴

Terry^{16, 18} has devised an ingenious experiment which offers considerable support to the view that the elliptical cells are more resistant to the action of hypotonic NaCl than the round cells. He allowed the blood to sediment and examined cells taken from the upper and lower layers of the blood. He found a greater percentage of ellipses at the bottom of the tube, and concluded that these cells were heavier. He then ran "fragility" tests on both layers of cells and found that, whereas the upper layer of cells (i.e., the round cells) gave resistance curves corresponding to the normal controls, the lower layer of cells (i.e., the ellipses) showed a much wider range, that is, hemolysis began in higher concentrations of NaCl, and was complete in lower concentrations. This type of curve is one frequently observed in menisocytic anemia. We have attempted to repeat his experiments but have not been able to get the elliptical cells to sediment. Blood taken from the lower levels, either in samples that had been centrifuged, or allowed to sediment, showed by actual counts no increase in the number of ellipses above counts taken from the topmost layers. Another explanation of Terry's findings has occurred to us. It is well known that reticulocytes and other young erythrocytes are more resistant to hypotonic saline solutions than are the older more "fragile" cells. These cells are also in all probability heavier than the more mature cells, since they contain traces of stroma and a larger amount of hemoglobin. In both of Terry's cases the reticulocytes were increased (8 per cent in one case). I would suggest that the resistance curves he obtained may be dependent on the increased numbers of immature erythrocytes in his preparations. It is of note that some of the other observers who found increased "fragilities" also found an increased number of reticulocytes and

formity under No. 0 cover slips, than in stained smears. Günther¹¹ has offered a rather ingenious explanation for this "rounding up" of ellipses when they are spread out, but to me it is not entirely conclusive. I have examined smears of camel's blood, kindly furnished me by Dr. Charles Noback of the New York Zoological Gardens. At the margins of these smears, and in areas where the cells are deformed by pressure from other cells, an occasional round cell is seen. Any one who routinely examines large numbers of blood smears has observed that there is frequently considerable variation in the shape and size of the cells in certain areas, even with the greatest care of glassware and the most constant technic.

The influence of chemical agents on the shape of the elliptical erythrocytes was studied as follows:

STUDIES IN THE SEROLOGY OF SYPHILIS*

XIII. THE USE OF THE SAME ANTIGEN FOR THE WASSERMANN REACTION AND THE AUTHOR'S FLOCCULATION TEST; AND A RECOMMENDED WASSERMANN TECHNIC

HARRY EAGLE, M.D., BALTIMORE, MD.

IN A previous paper of this series¹ I recommended the use of a more strongly fortified antigen in the Wassermann reaction, an alcoholic beef heart extract supersaturated with cholesterol (0.8 per cent) and sitosterol (0.6 per cent). This antigen was used in some 80,000 tests at the Johns Hopkins Hospital, and proved highly sensitive and specific. A distinct anticomplementary action of the 1:200 antigen dilution, due to the coarseness of the lipid suspension, was completely masked when one used 0.1 or 0.05 of serum in the test, in a total volume of from 0.05 to 0.06 c.c.

A flocculation test was subsequently devised² based on the use of a new sterol derived from corn germ as an adjunct to cholesterol, each sensitizer being added to a purified alcoholic beef heart extract in a concentration of 0.6 per cent. A priori, this flocculation antigen should prove equally serviceable in the Wassermann test, for the two antigens differ in no essential respect save the substitution of corn germ sterol for sitosterol. In actual practice, they have been found to yield practically identical results in a series of 2,630 Wassermann tests on approximately 400 patients with syphilis, and on approximately 1,300 patients with various diseases in a general hospital and dispensary population (Table I).

*From the Syphilis Division of the Department of Medicine, Johns Hopkins Medical School.

anomaly have been found in all four common blood groups. Three of our hospitalized patients were in Group III (Moss). The others were not typed.

Attempts to determine the etiology of the anomaly have so far proved unsuccessful. It cannot be transmitted from individual to individual by blood transfusion.⁶ Autopsies by Terry^{16, 18} and sternal punctures and splenic punctures by a number of observers^{9, 12, 15, 17} seem to offer definite evidence that the cells are not ellipses as they are formed, but as they mature they are subjected to the influence of some as yet unknown constituent of the plasma which causes them to assume their peculiar shape in the circulating blood. They are found in the vessels of the viscera (heart, spleen, and marrow spaces) as well as in the peripheral blood. Splenectomy did not affect the shape of these erythrocytes.¹⁰

The whole question of the factors influencing the shape of the erythrocyte and its peculiar constancy, is such an unsatisfactory one that we shall probably not be able to solve this problem of the shape of these elliptical cells until the more fundamental problems surrounding the usual shape of the erythrocyte are better understood. We need to know a great deal more about hematopoiesis and the mechanism of the release of the red cells into the circulation and their ultimate fate, before we can speculate further upon these questions. The question of nomenclature has been troublesome. We quite agree with Terry and his associates that this form of poikilocytosis should not be grouped with sickle cell anemia. Ovalcytosis and ovaemia have been suggested. Neither of these terms is entirely satisfactory but none better has been suggested.

Finally it may be said that this anomaly so far as we have been able to ascertain has no relationship to disease, in particular to the hemolytic anemias. It has been found in our series to occur in about 0.04 per cent of individuals. All our cases were in negroes.

STUDIES IN THE SEROLOGY OF SYPHILIS*

XIII. THE USE OF THE SAME ANTIGEN FOR THE WASSERMANN REACTION AND THE AUTHOR'S FLOCCULATION TEST; AND A RECOMMENDED WASSERMANN TECHNIC

HARRY EAGLE, M.D., BALTIMORE, MD.

IN A previous paper of this series¹ I recommended the use of a more strongly fortified antigen in the Wassermann reaction, an alcoholic beef heart extract supersaturated with cholesterol (0.8 per cent) and sitosterol (0.6 per cent). This antigen was used in some 80,000 tests at the Johns Hopkins Hospital, and proved highly sensitive and specific. A distinct anticomplementary action of the 1:200 antigen dilution, due to the coarseness of the lipoid suspension, was completely masked when one used 0.1 or 0.05 of serum in the test, in a total volume of from 0.05 to 0.06 c.c.

A flocculation test was subsequently devised² based on the use of a new sterol derived from corn germ as an adjunct to cholesterol, each sensitizer being added to a purified alcoholic beef heart extract in a concentration of 0.6 per cent. A priori, this flocculation antigen should prove equally serviceable in the Wassermann test, for the two antigens differ in no essential respect save the substitution of corn germ sterol for sitosterol. In actual practice, they have been found to yield practically identical results in a series of 2,630 Wassermann tests on approximately 400 patients with syphilis, and on approximately 1,300 patients with various diseases in a general hospital and dispensary population (Table I).

*From the Syphilis Division of the Department of Medicine, Johns Hopkins Medical School.

Received for publication, May 3, 1933.

The author therefore suggests that the use of the Wassermann antigen first described by him be discontinued, and that the same antigen* be used for both the Wassermann and precipitation tests. The Wassermann technic now in use is briefly outlined below.

It should be again³ pointed out that tests with highly sensitized antigens should not be incubated for more than four to eight hours in the ice box, as even 1:100 dilutions of the antigen are significantly anticomplementary upon overnight incubation. Nevertheless, as has been shown in the preceding paper of this series,³ a four hour ice box test with a highly sensitized antigen, followed by thirty minutes' incubation at 37° C., detects a larger proportion of syphilitic sera than an eighteen hour test with an antigen so weakly fortified as to be safe for overnight use. Moreover, with the technic outlined below, highly sensitized antigens have not been found to yield false positive reactions,³ other than the unavoidable technical slip-ups encountered in any laboratory with any technic, and which in a carefully analyzed series of 26,611 tests⁴ occurred about once in every 900 tests.

An Outline of Wassermann Technic

*Antigen.**—Fifty grams of dried powdered beef heart (Difco) are extracted for fifteen minutes at room temperature or at 37° C. with 200 c.c. anesthesia ether, with frequent shaking. The mixture is filtered, and the process repeated

TABLE I

RESULTS OBTAINED WITH THE FLOCCULATION USED AS WASSERMANN ANTIGEN, IN COMPARISON WITH THE WASSERMANN ANTIGEN ORIGINALLY DESCRIBED (2,630 TESTS)

	ABSOLUTE AGREEMENT 99%			RELATIVE AGREEMENT 0.5%		RELATIVE DIS-AGREEMENT 0.4%		ABSOLUTE DIS-AGREEMENT 0.1%

3 times. The moist powder is washed on the filter with 100 c.c. fresh ether, dried, and extracted with 250 c.c. of 95 or 96 per cent ethyl alcohol for three or five days at 20°-37° C. The mixture is then filtered, the moist powder washed with fresh alcohol until the filtrate is colorless, and the combined filtrate and washings are made up to 250 c.c. Cholesterol (1.5 gm.) and corn germ sterol (1.5 gm.) are then added and dissolved by boiling, a final concentration of 0.6 per cent for each. The antigen is used in the Wassermann test in a 1:100 dilution, prepared by slowly pouring 99 volumes of 0.85 per cent NaCl into 1 volume of antigen.

Complement.—The pooled serum of from 3 to 7 guinea pigs, allowed to stand on the clot overnight at 0°-4° C., is used in a 1:10 dilution.

Serum.—The serum to be tested is inactivated for twenty minutes at 56° C.

Cells.—Sheep's blood is collected in citrate† under sterile precautions. Cane sugar is then added in bulk to a concentration of 2.5 per cent. Kept in the

*The antigen or the corn germ sterol can be obtained from the Digestive Ferments Co., Detroit, Michigan.

†Twenty volumes of blood into 1 volume of sterile 20 per cent Na₂-citrate.

ice box, the cells remain in good condition for at least two weeks. This use of sugar to prolong the life of the cells was first suggested by Rous and Turner,⁵ but has unaccountably failed of general adoption. Not only does the sugar postpone spontaneous laking of the cells, but most important, because their resistance to hemolysis by complement is also maintained at a high level, the incidence of doubtful (so called 1+, 2+, 3+) results is greatly diminished.

The blood is washed once or twice in 10 volumes of 0.85 per cent salt solution, and the measured cell sediment resuspended in 32 volumes of salt solution, making a 3 per cent suspension. The minimal hemolytic quantity (unit) of amboceptor is then determined (Table II), and 3 units are added to the cells in an equal volume of salt solution, making a 1½ per cent suspension of sensitized cells.

TABLE II
AMBOCEPTOR TITRATION

Cells, 3%, c.c.	0.2	0.2	0.2	0.2	0.2	0.2	0.2
	1:400	1:800	1:1,200	1:1,600	1:2,400	1:3,200	
Amboceptor, c.c.	0.2	0.2	0.2	0.2	0.2	0.2	0
0.85 NaCl, c.c.	0.4	0.4	0.4	0.4	0.4	0.4	0.6
Complement, 1:10, c.c.	0.2	0.2	0.2	0.2	0.2	0.2	0.2

Reading of hemolysis after one-half hour at 37° C. complete complete complete complete complete partial none

Two-tenths cubic centimeter of a 1:2,400 amboceptor dilution therefore represents one unit. The entire 3 per cent cell suspension is then sensitized with an equal volume of 1:800 amboceptor, making a 1½ per cent suspension of cells sensitized with three units of amboceptor.

The tests are set up as outlined in Table III, and the tubes are placed for four hours in the ice box, *followed by one-half hour in the 37° C. water-bath.*

TABLE III
THE ROUTINE SERUM WASSERMANN TEST

	SERUM CONTROL	TEST	ANTIGEN CONTROL	COMPLEMENT CONTROL
Serum, c.c.	0.1	0.1 0.05	—	— — —
Complement 1:12, c.c.	0.2	0.2 0.2	0.2	0.2 0.1 0.05
Antigen 1:100, c.c.	—	0.2 0.2	0.2	— — —
0.85% NaCl, c.c.	0.2	— —	0.2	0.4 0.5 0.5

From four to six hours at 0°-5° C., followed by one-half hour at 37° C. Then add 0.4 c.c. sensitized cells. Read results after twenty or thirty minutes at 37° C.

TABLE IV

QUANTITATIVE WASSERMANN TEST FOR THE EXACT TITRATION OF A KNOWN POSITIVE SERUM

	SERUM CONTROLS		TEST PROPER							
Serum, c.c.	0.2	0.05	0.2	0.05						
Serum 1:25, c.c.					0.4	0.2	0.1	0.05	0.025	0.0125
Complement 1:10, c.c.	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2
Antigen 1:100, c.c.	—	—	0.2	0.2	0.2	0.2	0.2	0.2		
NaCl, 0.85%, c.c.	0.2	0.2		0.2					0.2	0.2

Complement and antigen controls as in Table III. The six tubes correspond to serum dilutions of 1, 1:4, 1:12, 1:25, 1:50, 1:100; and the reagin content of any serum may be arbitrarily expressed as the maximum dilution yielding a positive result. Thus, a reading of 44440 corresponds to a reagin titer of 50; a reading of 444420, to a titer of approximately 35, and so on.

Four-tenths cubic centimeter of the sensitized cell suspension is then added to all the tubes. The antigen controls should clear within ten minutes. The complement controls containing 0.2 and 0.1 c.c. of complement, should both hemolyze completely within one-half hour, while that containing 0.05 c.c. of complement should not, inasmuch as the three units of amboceptor automatically correspond to $2\frac{1}{2}$ or 3 units of complement. The results of the test may be read within five

TABLE V
SPINAL FLUID WASSERMANN TECHNIC

	CONTROLS		TEST PROPER

Spinal fluid 1:10, c.c.											
Complement 1:10, c.c.	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2
Antigen 1:100, c.c.			0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2

Four hours at 0°-5° C., followed by one-half hour at 37° C. Add 0.4 c.c. sensitized cells. Read after twenty or thirty minutes at 37° C.

minutes of the time the antigen controls have cleared, about twenty or thirty minutes in all. If neither tube of the test shows any evidence of hemolysis, the result is *positive*; if either tube shows partial hemolysis, the result is *doubtful*; if both tubes are completely hemolyzed, the result is *negative*.

For the quantitative titration of a known positive serum, the same test is carried out on a series of serum dilutions as outlined in Table IV. The spinal fluid technic is outlined in Table V. It need be carried out routinely only down to 0.05 c.c., but it is advisable to add the last three tubes with spinal fluids containing abnormally high quantities of protein.

SUMMARY

Properly diluted, the flocculation antigen described by the author has been found to be equally serviceable in the Wassermann reaction. The results are as sensitive and specific as those obtained with the highly fortified Wassermann antigen described in a previous paper of this series. It is therefore suggested that the use of the latter be discontinued, and the same antigen be used in both the Wassermann and flocculation tests. A recommended Wassermann technic is outlined.

A PROBABLE UNUSUAL CASE OF HODGKIN'S DISEASE*

DONALD C. BEAVER, M.D., AND WALTER R. JOHNSON, M.D.
ROCHESTER, MINN.

SUCH unusual clinical and pathologic diagnostic problems were presented in the case to be reported here, that it seemed desirable to place it on record. The clinical features of the illness were those of an acute infectious process characterized by continued fever, weakness progressing to exhaustion, abdominal distention without pain, and diarrhea, all suggestive of a typhoid state, but with repeatedly negative Widal tests. The pathologic changes were characterized primarily by proliferation of reticulo-endothelium and lymphocytes, and extreme necrosis, with involvement of the liver, spleen, and abdominal lymph nodes. The pathologic interpretation of these changes was as difficult as the clinical interpretation of the syndrome. Extreme necrosis had obscured the picture almost to the point of nonrecognition. The differential identification of inflammatory granulomas such as occur in tularemia and undulant fever, from Hodgkin's granuloma or a sarcomatous neoplasm was not easily made. Finally, after prolonged study of multiple histologic preparations, we concluded that we were dealing either with an unknown granulomatous process or, as seemed more likely, an unusual manifestation of Hodgkin's disease.

REPORT OF A CASE

The patient was an unmarried white woman, aged twenty-six years, whose entire life had been spent in southern Minnesota. In childhood she and an older brother had been victims of an epidemic of catarrhal jaundice which had swept the community, but recovery had been prompt and uncomplicated. She had experienced the usual infectious diseases of childhood, and had always suffered from a "weak stomach," according to her mother. Nausea, regurgitation, or vomiting often followed excessive excitement. She had pursued an uneventful life until she was aged twenty-two years, at which time symptoms of peptic ulcer appeared. These symptoms had become so severe that six months after their onset, subacute perforation was suspected, and she was taken to a large city for observation in a hospital. Exploration had been carried out after several weeks of observation, and posterior gastroenterostomy performed. The exact nature of the lesion found by the surgeon had not been revealed to the patient or to her family. Recovery had been slow, and the patient found it necessary to observe considerable care in her diet for several years. She had been able to resume work as clerk in a postoffice, and for two years had fair health. During the spring and summer of 1931, she had become exhausted more easily than usual. In September, 1931, she had been confined to bed for several days because of general malaise and slight diarrhea. She had returned to her work, and although she felt definitely below par, was able to continue her duties for two or three weeks.

In the first week of October, gradual distention of the abdomen had begun, with the development of obstinate constipation and weakness. The patient's physician at home had been called October 11 because of persistence of these symptoms. He had been unable to ob-

*From the Section on Pathologic Anatomy and Division of Medicine, The Mayo Clinic.
Received for publication, May 9, 1932.

tain any more significant history than that already detailed; there had been no history of pain at any time during the recent illness. His examination had disclosed only marked tympanites and an elevation of temperature to 100° F. For a week, the patient's temperature had varied from 100° to 104° F. On two occasions it had been found to be 104° F. at 4 A.M. and 99° F. five hours later. The patient had been able to take light nourishment by mouth. Some green-colored fecal material had been obtained by repeated enemas, but the abdominal distention remained unchanged. The patient's condition gradually had become worse, and she was irrational at times. From October 18 to 21 she had passed each day, spontaneously, three or four stools of the appearance of pea soup. Her condition at this time had strongly suggested typhoid fever, a condition with which her local physician was familiar, but four successive Vidal tests were reported negative.

The patient was brought to Rochester in a state of shock October 21. Examination in the hospital revealed pallor of the extremities and face; she was bathed in cold perspiration. Her abdomen was hugely distended and tympanitic. Few, if any, intestinal sounds could be heard. The rate of her pulse was 100 beats each minute; its quality was thin and thready. Blood pressure in millimeters of mercury was 88 systolic and 66 diastolic. Respiration was shallow, and her breath had a sour odor. She was comatose, but could be aroused enough to open her eyes. The pupils were small and reacted slightly to light. The Achilles tendon reflexes were absent. The neck was not rigid, and Kernig's sign could not be elicited.

Immediate supportive measures to combat shock were instituted. Solution of acacia and glucose were administered intravenously. Studies of the blood revealed that erythrocytes numbered 4,500,000 and leucocytes 7,100 in each cubic millimeter; the concentration of hemoglobin was 68 per cent (Dare); the concentration of urea was 36 mg. and of sugar 0.09 gm. in each 100 c.c. of blood. Agglutination tests for typhoid fever, paratyphoid fever, and undulant fever gave negative results. The state of shock persisted; the pulse rate rose to 130 beats each minute, and the blood pressure decreased. Death occurred a little more than twenty-four hours after admission.

Careful questioning of the patient's immediate family revealed only three features regarding possible contacts or exposures: (1) In the year previous to her final illness, the patient had made several visits to a neighboring farm where a rabbitry was maintained. (2) There was rather close association with a pet cat. (3) The final illness appeared at the time of extensive floor varnishing in the patient's home. The fumes from the varnish were said to have made the patient very ill, but other members of the family were not thus affected. The milk supply was investigated and found to come from the local dairy, which supplied most of the milk to the village. It was said to have been pasteurized. There was no history of bites or scratches of animals, or of bites of flies or ticks. There were no endemic diseases with which the patient was known to have had contact.

Macroscopic Findings at Necropsy.—Necropsy was performed two hours after death. The body had not been embalmed. Its length was 5 feet, 4 inches (163 cm.), and the estimated weight 135 pounds (61 kg.). The abdomen was moderately distended. There was slight edema of both lower extremities.

The left pleural cavity contained 500 c.c. and the right, 350 c.c. of clear, amber-colored fluid. The lungs were normal, except for calcified subpleural tubercles which were present in the right lung. The lymph nodes of the hilum of the right lung contained caseous, fibrous, and calcified tubercles. The pericardial sac contained 75 c.c. of light, greenish-yellow, clear fluid. The heart weighed 205 gm. The free edge of the mitral valve was moderately thickened, and presented very small, rounded, firmly attached elevations such as characterize rheumatic endocarditis. The myocardium appeared to be normal.

The peritoneal cavity contained 2,000 c.c. of clear, amber-colored fluid.

The spleen weighed 390 gm. The surface presented multiple rounded, slightly elevated nodules, which varied from 1 mm. to 3 cm. in diameter. These nodular areas appeared not to differ in color from the intervening depressed areas; both were purplish. The consistency of the nodules was much increased over that of the depressed portions. The appearance and size of the nodules were similar on the sectioned surface, except that they were commonly

surrounded by a hemorrhagic zone which clearly demarcated them, and their centers were usually grayish-white. The central portions suggested zones of necrosis without softening.

The liver weighed 2,250 gm. and extended 4.5 cm. below the costal margin. Small, grayish-white, slightly elevated nodules were observed on the capsular surface. These alternated with normal-appearing capsule, or with areas of dark red mottling. The nodules varied from 1 mm. to 2 or 3 cm. in diameter. The sectioned surface presented a similar appearance (Fig. 1). Little normal parenchyma was identifiable. The nodular appearance, so clearly revealed on the capsular surface, was less prominent on the sectioned surface, due to confluence of the grayish-white areas and also to their less discrete peripheral differentiation from the surrounding parenchyma or from the hemorrhagic, mottled zones. The gallbladder, bile ducts, and hilar vessels were normal.

The rugae of the stomach were hypertrophic, and the gastric mucosa was moderately congested. A stoma resulting from posterior gastroenterostomy was present, and appeared to be in good condition. A puckered scar, representative of a healed duodenal ulcer, was found on the posterior wall of the first portion of the duodenum. The jejunal and cecal mucosa presented multiple, small, petechial hemorrhages, with a small amount of free blood in the lumen of the bowel. The remainder of the gastrointestinal tract appeared normal.

Fig. 1.—Gross appearance of the liver.

Surrounding the head of the pancreas, lesser curvature of the stomach, hepatic hilum, and aorta, retroperitoneally from the diaphragm to the bifurcation, the lymph nodes were moderately to markedly enlarged. They were firm, and grayish-white to light pink, with a glistening appearance when sectioned. Lymph nodes in other anatomic situations appeared to be normal. The pancreas, suprarenal glands, kidneys, pelvic viscera, thyroid gland, thymus, great vessels, and brain appeared normal.

Microscopic Findings at Necropsy.—Sections were prepared from tissue which had been fixed in Orth's fluid and embedded in paraffin. All were stained by hematoxylin and eosin, from which the detailed descriptions of the microscopic changes were made. Selected tissues were also stained for microorganisms by Giemsa's method, by Gram's method (Brown's modification), by Loeffler's methylene blue, by carbolfuchsin and methylene-blue acid-fast stain, and by silver impregnations (de Galantha method) for the demonstration of spirochetes.

The most striking feature of the hepatic lesion was extreme necrosis of the parenchyma (Fig. 2A). The necrosis apparently involved from half to two-thirds of the entire hepatic substance. This varied in degree in the various regions, from complete destruction of hepatic parenchyma to preservation of groups of cells surrounding the portal spaces, or to the preservation of larger units up to entire lobules or groups of lobules. The zones of necrosis were sharply demarcated from the preserved hepatic tissue, and in the necrotic zones usually no

trace of hepatic cells existed, they apparently having rapidly undergone autolysis, leaving dust-like chromatin particles in the necrotic regions. Intact hepatic units were never found in the central lobular zones to the exclusion of other parts of the lobule. The portions of the liver which were sharply demarcated from the necrotic fields revealed no retrogressive changes. The hepatic reticulum was not involved by the necrosis; the sinusoidal structures were still intact and engorged with blood. Hemorrhage, sometimes present in the necrotic portions, was caused not only by intense sinusoidal congestion but also by breaking down of some sinusoidal membranes or by engorgement of the central lobular vascular bed. Occasional proliferation of reticuloendothelium was observed. Aggregations of cells were identified, sometimes about the portal spaces or as isolated groups of cells near the periphery of the necrotic zones (Fig. 2*B*). In these cellular collections lymphocytes predominated, but large mononuclear leucocytes and endothelial cells were also found (Fig. 3*A*). Some of the endothelial cells and mononuclear leucocytes were giant forms, with either a single, large, clear nucleus, or with several small hyperchromatic nuclei. They had frequently phagocytosed lymphocytes or erythrocytes. Only occasionally were collections of lymphocytes found in the areas of necrosis. The walls

Fig. 2.—*A*, Extreme necrosis of hepatic parenchyma. Hematoxylin and eosin ($\times 45$); *B*, Collections of cells in portal connective tissue and at the periphery of necrotic zone. Hematoxylin and eosin ($\times 400$).

of the portal veins, and to some extent of the hepatic arteries, often contained cells similar to those described in the focal collections. In these vessels, too, proliferation of endothelial cells was often a prominent feature. Recently formed thrombi were observed in some of the medium-sized portal veins. The bile ducts were not involved.

The splenic sinuses were dilated and intensely engorged with blood. Malpighian follicles were decreased in number, and in those which had survived the lymphocytes were fewer, as were the lymphocytes of the splenic pulp. The second feature of note in the microscopic preparations was necrosis. This appeared as distinctly circumscribed zones, varying in size and shape, of granular, eosin staining material, which were either completely devoid of cellular structure, or zones in which only the faded outlines of cells were visible. Chromatin material often appeared in the central portion as dust-like particles. Sinuses at the periphery of the necrotic zones were congested. The third feature of note was the collection of cells which surrounded the necrotic fields (Fig. 3*B*), or appeared as small foci in the surrounding regions. Lymphocytes, mononuclear leucocytes, endothelial cells, and sometimes proliferated reticulum composed these collections. As in the liver, some of the mononuclear leucocytes and endothelial

cell types were multinucleated. Lymphocytes usually predominated (Fig. 4A). In many endothelial cells and mononuclear leucocytes were phagocytosed erythrocytes, lymphocytes, and cellular detritus. Endothelial cells were commonly increased in number, in the veins, arteries, arterioles, and sinuses. These were so numerous in some instances that the lumens of vessels or sinusoids were occluded. When this condition prevailed in the arteries and veins, the vascular walls were edematous, and frequently lymphocytes and large mononuclear leucocytes

Fig. 3.—A, Lymphocytes, mononuclear leucocytes, and endothelial cells composing the cellular collections of the liver. Hematoxylin and eosin ($\times 400$). B, Cellular collection surrounding necrotic zone of spleen. The cells are chiefly lymphocytes, but mononuclear leucocytes and endothelial cells are also present. Hematoxylin and eosin ($\times 230$).

Fig. 4.—A, Fibroblasts and endothelial cells sometimes predominated in the foci of the spleen. Hematoxylin and eosin ($\times 300$). B, Necrosis with disorganization and exhaustion of lymphoid elements of nodes. The reticulum is prominently displayed. Hematoxylin and eosin ($\times 435$).

had invaded the walls. Perivascular collections of these cellular types were also present around vessels so affected. Recently formed thrombi were present in some of the veins.

The distinctive characteristics of the lesions in the gastric, hepatic, pancreatic, and retroperitoneal aortic lymph nodes, as in the liver and the spleen, were proliferative granulomatous reactions with extensive necrosis. The medullary portions of the nodes were most severely involved, where almost complete exhaustion and disorganization of the lymphoid elements

Fig. 5.—A, Dilated sinusoids of lymph node in which large endothelial cells and lymphocytes can be seen. Hematoxylin and eosin ($\times 575$). B, Local collection of lymphocytes, mononuclear leucocytes, and endothelial cells. Hematoxylin and eosin ($\times 145$).

Fig. 6.—Cellular collections in the capsule of a lymph node. Hematoxylin and eosin ($\times 95$).

existed (Fig. 4B). In the cortical portion the changes were less intense, but nevertheless severe, and in this portion but few intact lymph follicles could be found. The sinusoids and reticulum were everywhere prominently displayed, due to the loss of lymphoid elements. The sinusoids were often seen as dilated spaces devoid of cells, but some contained a few cells, whereas others were engorged with cells, among which were lymphocytes, mononuclear leucocytes, erythrocytes, and large endothelial cells. The last named cells predominated (Fig. 5A).

They were distinguished usually by acidophilic cytoplasm and vesicular nuclei with a few multinucleated forms. In some, phagocytosed erythrocytes, lymphocytes, and cellular detritus were identified. Proliferated reticular cells were sometimes also revealed in the same zones. Within the medullary portions the sinuses were usually devoid of cells, or contained but few cells, whereas in the cortical portions engorgement was not infrequently observed. Focal collections of lymphocytes, large mononuclear leucocytes, and endothelial cells were also present throughout the nodes (Fig. 5B). These collections were likely to be found in any portion of the node but were usually at the periphery of the necrotic fields. Commonly, however, they were observed in the cortex, where they formed a peripheral, encircling zone from which they also extended into the capsule and surrounding tissue (Fig. 6). Within the fields of necrosis few such collections existed. Many lymph and blood vessels of the capsule contained excessive numbers of lymphocytes, mononuclear leucocytes, and endothelial cells, in addition to erythrocytes. Thrombi were sometimes present in the blood vessels. Perivascular zones of the capsule were particularly prone to reveal large increases of lymphoid cells and large mononuclear leucocytes sometimes with extravasated erythrocytes. In some of the capsules of lymph nodes, these reactions were diffuse, although rarely were they dense.

Sections of the lungs were essentially normal, but lymph nodes obtained from the hilum of the right lung disclosed tuberculous involvement. These lesions were quiescent and essentially healed.

The mitral valve was involved by a chronic, proliferative inflammatory reaction, with formation of small, hyaline-like vegetations along the line of closure.

The preparations of tissue, stained for bacteria, did not disclose convincing evidence of causation. As is well known, such preparations are sometimes difficult to interpret, and may lead to erroneous conclusions. In the stained preparations from the mitral valve and lymph nodes, small, gram-positive and gram-negative diplococci were seen. In the spleen and liver an occasional gram-positive coccoid form was revealed, but they were so few that their significance could not be emphasized. Search for other types of microorganisms by the various staining methods listed was fruitless.

Cultures in brain broth and blood agar were prepared from the blood and splenic pulp. No growth appeared. The brain broth was allowed to incubate at 37.5° C. for three weeks. Serum taken from the blood failed to agglutinate antigens prepared from *Bacterium tularensis* or *Bacterium abortus*.

COMMENT

This case presents several features in common with that reported in 1921 by Loygue and Clarion. Their patient, a soldier aged twenty years, died after an illness lasting three months, the clinical course of which was quite similar, in many respects, to that detailed for our patient. At necropsy they found the liver and spleen to be diffusely enlarged. Two large masses of lymph nodes were found, one in the gastrohepatic omentum, the other along the abdominal aorta. In addition, masses of discrete lymph nodes were found in the left axillary and cervical regions. After careful study the authors decided that tuberculosis and malignancy were definitely ruled out. Hodgkin's disease was thought to be inadmissible because of the rapid febrile course and the absence of the typical microscopic picture. They concluded that their patient died of an infectious granulomatous process of unknown etiology, but it seems likely, from their description of the microscopic findings, that they were actually dealing with a case of atypical Hodgkin's disease.

A somewhat similar case was reported by Spangenberg in 1929. The liver and spleen were enlarged and huge masses of discrete lymph nodes were found along the abdominal aorta and extending from the hilum of the spleen to the liver. Syphilis, malignancy, and tuberculosis were definitely ruled out.

Hodgkin's disease could not positively be diagnosed because of the absence of typical Sternberg cells. Diffuse lymphoid hyperplasia was the term finally selected to describe the lesion.

In our case all available clinical and pathologic data were applied to the problem of differential diagnosis. Certain infectious diseases, such as tularemia and undulant fever had to be considered. Tularemia seemed to be excluded by the negative agglutination tests obtained from the blood, postmortem. Furthermore, there was no history of contact with wild rabbits, and although the patient had visited a local rabbitry on several occasions, no case of tularemia from contact with domesticated rabbits has thus far been recorded. One case in Francis' experience resulted from the scratch of a cat, but such an occurrence was not recorded in the history of our case. Undulant fever seemed to be ruled out by virtue of negative agglutination tests made while the patient was alive and negative cultures made from the blood and spleen, postmortem. Typhoid fever and paratyphoid fever were eliminated from consideration because of the repeatedly negative agglutination tests and blood cultures and the absence of lesions in the intestines and mesenteric lymph nodes. Tuberculosis, actinomycosis, glanders, leprosy, and blastomycosis were excluded not only because of the gross and histologic characteristics of the lesions, but also because of our failure to demonstrate the specific microbes of these diseases. Rickettsia diseases such as typhus and Rocky Mountain spotted fever, so far as is known, do not occur in Minnesota and were excluded from consideration because of lack of clinical and postmortem evidence of cutaneous involvement. Furthermore, the severe changes in the spleen, liver, and lymph nodes, as revealed in our case, are not recorded for these diseases. Syphilis was considered but was excluded on the basis of absence of significant history and vascular changes and negative stains for spirochetes. The various types of leucemia were ruled out because of the absence of anemia, usually an accompaniment of acute leucemia, absence of leucocytosis, and, more especially, because the lesions in no way resembled the visceral lesions of leucemia.

A finding of questionable significance was the presence of microorganisms interpreted as diplococci in the tissues of the lymph nodes and mitral valves. The negative cultures from the blood of the heart and spleen, taken postmortem, discount the significance of such a finding. Absence of the inflammatory reactions usually considered as characteristic of conditions caused by such organisms was further evidence serving to negate the importance of this finding.

There was little evidence to support the theory that the lesions might be due to a toxic substance in the fumes of floor varnish.

A conclusion that the tissue reactions were an unusual manifestation of Hodgkin's disease or lymphosarcoma rather than one of the other diseases named or of an unknown type of infectious granuloma was finally reached as much by a process of elimination as by positive evidence. Hodgkin's disease seemed to fit into the picture better than lymphosarcoma because the pathologic process was distinctly visceral and was confined to the liver, spleen, and ab-

dominal lymph nodes. It was distinctly reticuloendothelial in its distribution and it lacked the anaplastic features one would expect in lymphosarcoma. The features which supported a diagnosis of Hodgkin's disease were: (1) proliferation of reticuloendothelial cells in and about the lesions; (2) proliferation and aggregation of lymphocytes and mononuclear leucocytes, and (3) the occurrence of giant cell types of endothelial cells and mononuclear leucocytes which resembled the Sternberg (Dorothy Reed) cells of Hodgkin's disease. The extreme necrosis, thrombosis, and perivascular collections of cells are not usually seen in Hodgkin's disease, but they do not render such a diagnosis untenable. The clinical history, although atypical, conforms in some ways with that seen in cases of visceral Hodgkin's disease. Fever is not an uncommon finding in some cases of Hodgkin's disease. The rather rapid course of the disease is unusual but in this instance may be accounted for by the extreme involvement of the liver.

In conclusion it seems best to classify our case as one of atypical Hodgkin's disease. It is apparent that our case presents many features in common with the case reported by Spangenberg and particularly with the one described by Loygue and Clarion. It would be impossible, however, to state that these three cases are clinically, etiologically and pathologically identical.

THE PARTITION OF POTASSIUM BETWEEN THE SERUM AND CORPUSCLES IN HEALTH AND DISEASE*

WILLIAM S. HOFFMAN, PH.D., M.D., AND H. R. D. JACOBS, M.D., CHICAGO, ILL.

POTASSIUM IN CORPUSCLES AND SERUM

IN 1922, Kramer and Tisdall¹ found that the potassium concentration in human serum was 18 to 22 mg. per 100 c.c., while that of human red cells was about 428 mg. per 100 c.c. They showed that, except for a small amount of magnesium, potassium was the only cation in the red cells, and intimated that it balanced osmotically the cations of the plasma. Their values for normal serum have been corroborated many times, but their values for red cells have received little attention.

*From the Department of Medicine, Rush Medical College of the University of Chicago. Received for publication, May 20, 1933.

The reason for the maintenance of such constant values for both red cells and serum is not apparent. But this peculiar partition suggests a physiologic balance which might be disturbed in disease. It was with this possibility in mind that a brief survey of the potassium concentration of red cells and serum in disease was undertaken. In order to facilitate this study, a new method for the determination of potassium in whole blood was devised.

METHODS

The concentration of potassium in serum was estimated by the method of Jacobs and Hoffman.² Serum total base was determined in a phosphate-free, protein-free filtrate obtained from serum by the method of Hoffman.³ In this method, coagulation by heat of the proteins of the diluted serum is effected at the iso-electric point, with the simultaneous precipitation of phosphates by the addition of ferric chloride and ammonium acetate. The results obtained are about 1 per cent too high because of slight evaporation of the hot liquid and because of the slight change in volume when the proteins are precipitated. The average value for normal serum total base, after correcting by subtracting 1 per cent, was 155.3 m.eq. per liter, and the extreme variations were 152.7 and 158.6 m.eq. per liter.

Serum chloride was determined according to Van Slyke,⁴ and calcium according to Tweedy and Koch.⁵ All other routine chemical data were taken from hospital charts. Hematocrit readings were made with Van Allen capillary pipettes,⁶ using 1.3 per cent sodium oxalate as an anticoagulant and diluting fluid.

For the whole blood potassium, a new method was devised in which the time-consuming and hazardous operation of ashing was eliminated. This was accomplished by the preparation of a suitable protein-free filtrate from whole blood by a modification of the basic ferric acetate method of deproteinization in Hoffman's³ technic for the determination of the total base of serum.

Procedure for Whole Blood Potassium.—In a 50 c.c. volumetric flask, 2 c.c. of freshly drawn whole blood were laked in about 40 c.c. of water. To this mixture were added 1 c.c. of ferric chloride reagent (A),* 1 c.c. of sodium acetate reagent (B),* and one drop of iso-amyl alcohol. The mixture was diluted with water to the mark and thoroughly shaken. About 20 c.c. were transferred to a large Pyrex test tube and heated rapidly to boiling. At the boiling point, the mixture separated into dense brownish red curds and a water-clear solution. It was filtered immediately through a double No. 40 Whatman filter paper. Filtration was very rapid. The water-clear filtrate contained no protein, no lipoids, no phosphate and no iron. It contained nothing that would interfere with the direct precipitation and determination of potassium. Its P_{H} was about 5.5.

Since the red cells contain most of the potassium, the concentration of potassium in whole blood varies with the red cell volume or is inversely proportional to the degree of anemia. For normal or nearly normal persons, 2 c.c. of filtrate contain a quantity of potassium adequate for accurate determination. If, however, there is marked anemia, that is, if the hematocrit is below 30 per cent, 4 c.c. of filtrate are required. The determination was carried out from this point on by the method employed for serum.†

*A. Ferric Chloride Reagent: Dilute 100 c.c. of 10 per cent $FeCl_3 \cdot 6H_2O$ in 0.2 N HCl to one liter with water.

B. Sodium Acetate Reagent: Dilute 100 c.c. of 15 per cent $NaC_2H_3O_2 \cdot 3H_2O$ and 20 c.c. of 1.4 N NaOH to one liter with water.

†Since the publication of our colorimetric method for the estimation of potassium, we have had occasion to make more than a thousand potassium determinations on whole blood, serum, and inorganic solutions. We have found the method consistently reliable. The technic as described will accurately determine potassium in concentrations varying from 10 to 40 mg. per 100 c.c., and can be easily adjusted for higher concentrations. The limitations of the method are those of the Kramer-Tisdall technic for the precipitation of potassium, which have been thoroughly discussed by Peters and Van Slyke.⁷ In particular, the authors have found that when potassium in concentrations of the order of 40 mg. per 100 c.c. is precipitated in the absence of sodium (which condition occurs at times in samples of ashed urine from nephrotic patients), high results are obtained. Along with Hubbard,⁸ the authors have recognized that this error can be avoided by the addition of extra sodium, especially as sodium acetate. The filtrate from whole blood, it will be noticed, contains sodium acetate, and this fact may be partly responsible for the consistent results obtained.

From the values for potassium in serum and in whole blood and from the red cell volume, the potassium content of red cells can be computed by the following formula:

$$\text{Whole Blood K} - \frac{100 - \text{Vol. per cent of cells}}{100} \times \text{Serum K} \times 100 = \frac{\text{Volume per cent of cells}}{\text{Volume per cent of cells}} \times 100 =$$

Potassium per 100 c.c. of red cells. For example: Serum K, 20.4 mg. per 100 c.c.; Whole Blood K, 201.4 mg. per 100 c.c.; Cell volume, 44.5 per cent; then,

$$\frac{201.4 - \frac{100 - 44.5}{100} \times 20.4}{44.5} \times 100 = 427.7 \text{ mg. K per 100 c.c. of red cells.}$$

The sequence used in taking samples was the following: Venous blood was drawn with-out stasis into a freshly cleaned and baked syringe. The blood was transferred into freshly cleaned and baked centrifuge tubes. Two cubic centimeters of blood were quickly transferred by means of a Folin-Ostwald pipette to the 50 c.c. volumetric flask containing about 40 c.c. of water. Then two Van Allen hematocrit tubes were prepared by first drawing up blood to the 100 mark, then by diluting it with 1.3 per cent sodium oxalate and finally by enclosing the tube in a tight-fitting, wide rubber band. All these operations had to be completed before clotting had set in. The Van Allen tubes were centrifugated for twenty minutes at 3,000 r.p.m. before reading. The blood in the centrifuge tubes was allowed to stand for fifteen minutes at 37° C. and then centrifugated. The serum separated was again centrifugated to remove all red cells. No serum was used which had any recognizable trace of hemolysis. All determinations were made in duplicate and were discarded if they did not check.

RESULTS

Table I presents data showing the adequacy of the new method for the determination of whole blood potassium. The results were less than 0.5 per cent higher than those obtained by the use of ashed whole blood. Added potassium was accurately recovered.

The distribution of potassium between serum and corpuscles was first studied in thirty normal persons. There were 17 men and 13 women, ranging in years from nineteen to thirty-nine. The determinations on women were made when they were not menstruating. The results are presented in Table II. The serum potassium averaged 19.3 mg. per 100 c.c. and the red cell potassium 422.7 mg. per 100 c.c. The individual values for the serum fell around the average within very narrow limits and corresponded with those obtained by other authors. The results for red cells fluctuated somewhat, but the standard deviation was only 3.3 per cent. There were two low values with deviations of 7 per cent and one high one with a deviation of 9.5 per cent. The values when charted for frequency (Fig. 1) do not closely approximate the theoretical probability curve, but such an approximation is hardly to be expected, since only

Fig. 1.—Composite frequency chart of red cell potassium concentrations in normal and diseased persons. Solid circles indicate red cell values associated with serum total base of 15.3 m.eq. per liter or less.

thirty determinations were made and since the sources of error are not only the individual physiologic variations, but also the technical errors of both the potassium determination and the hematocrit estimation. Nevertheless, the results obtained for cell potassium concentration agree closely with those obtained by Kramer and Tisdall who used a different technic.

Table III presents 27 cases of various diseases. The results obtained both for serum and red cells showed no wider deviations from the normal mean than those on normal individuals. In the cases of anemia, in spite of marked variations in whole blood potassium, cell potassium was practically always within normal limits.

Of the six cases of pneumonia reported in Table IV, two had high cell potassium concentration, which, in one case at least, was associated with a high total base concentration in the serum.

Fourteen determinations on pregnant women are shown in Table V. Here, too, the average values agreed closely with those for normal persons. The variations of the red cell potassium values, however, were greater than those in the normal group, four lying at or near the lower limits of normal. The average red cell potassium was found to be slightly lower than normal, but the deviations were small as compared with those reported by Rossenbeck,⁹ who found in normal pregnancy low serum potassium, low sodium, and high chloride. Spiegler,¹⁰ on the other hand, has reported high serum potassium values in normal pregnancy.

The nine cases of thyroid disturbance given in Table VI are too few to prove any definite tendencies. The results obtained showed no evidence of altered serum potassium concentration such as has been reported in thyroid disturbances.¹¹

Table VII presents the results on patients with clinical nephrosis. Three showed no signs of kidney inefficiency, while one apparently was in the nephrotic stage of chronic glomerulonephritis. In those whose edema had subsided both

serum and red cell potassium were essentially normal. Serum total base and chloride values were at the upper limit of normal. One patient, however, with intractable edema (Case 90) had low red cell potassium at the time the total base and chloride of the serum were low. Potassium chloride ingestion produced a simultaneous rise in both cell potassium and serum total base, associated with a slight diuresis. Later, after ammonium chloride ingestion had produced an acidosis, the low total base and low red cell potassium were unaffected by the administration of potassium citrate. The retained potassium produced only a rise in serum potassium. The significance of these results in relation to edema are further discussed in a paper by Hoffman and Post.¹²

Table VIII contains fifteen determinations in cases of azotemic Bright's disease. Six were probably cases of chronic glomerulonephritis, while the rest were for the most part cases of nephrosclerosis with or without other compli-

eations. Four cases of azotemia associated with prostatic obstruction are included. The cases of chronic glomerulonephritis in uremia usually had low cell potassium together with low serum total base. These patients all had profound anemia, and had been vomiting enough to produce marked dehydration. The serum potassium in these cases varied in both directions from normal. The highest serum potassium concentration of all (38.4 mg. per 100 c.c.) was found in a patient (Case 27) who had been given potassium citrate for several days. In this case the red cell potassium was only 300 mg. per 100 c.c. In the other cases in this table the findings varied. Most of these patients were older than those with glomerulonephritis. They usually had a high serum potassium comparable to their nitrogenous retention, and their red cell potassium also tended to be high, particularly where there was mechanical obstruction. Their serum total base was also usually high. However, the whole group presented a number of apparently inconsistent findings, so that it was impossible to draw any rigid generalizations.

In Table IX are shown the results obtained in seven cases of allergic bronchial asthma before and after epinephrine injection. The studies were made, wherever possible, at the time of the attack and when the influence of previous injections of epinephrine had disappeared. In all cases the serum potassium values were found to be higher than normal. They were lowered within twenty minutes after the injection of ten minims of epinephrine. The lowest serum potassium of all (14.8 mg. per 100 c.c.) was found in a twenty-year-old girl ten minutes after the first injection of epinephrine for the relief of an attack of incipient asthma. This patient at the time was in a state of high nervous irritability. Unfortunately it was impossible to repeat the determination. The red cell potassium concentrations in all cases were within normal limits and were not appreciably affected by the injection of epinephrine.

COMMENT

Including the 30 determinations on normal adults, a total of 112 determinations of the distribution of potassium between red cells and serum have been made. It is obvious that the data are too meager to allow many generalizations. Yet certain facts are apparent. In the first place, the concentration of potassium in both red cells and serum remains remarkably constant in health and disease. In all the conditions studied, with the exception of Bright's disease and asthma, there were no wide variations from the average normal values (see Fig. 1). Even in anemia, though the whole blood potassium might be half of the normal concentration, the values for both serum and red cells were not particularly altered.

In those cases in which the red cell potassium deviated from the normal, certain other factors were present which might individually or collectively be responsible for the variations. The low red cell potassium found in most of the cases of uremia, especially in chronic glomerulonephritis, was associated with at least two other almost constant findings, low serum total base and profound secondary anemia. That there might be a correlation between serum total base and red cell potassium is suggested not only by these findings, but by a general, if not consistent, trend of low serum base with low red cell potassium. In the frequency chart (Fig. 1), the cases associated with total base of 153 m. eq. per liter or lower are found to be well on the side of low cell potassium. The attempted correlation is probably not fair, since the possible relationship was not discovered until rather late in the studies, so that total base determinations are incomplete. Nevertheless, the limited findings suggest that serum total base parallels the red cell potassium, a relationship which has a theoretical plausibility.

The degree and type of anemia may also possibly be a factor in determining the level of red cell potassium. The technical error in the determination of cell potassium increases with the degree of anemia, since the hematocrit error is increased and the concentration of potassium in the filtrate is dimin-

ished. However, it was found in general that the secondary anemia of nephritis as well as of other diseases gave rather low red cell potassium values, whereas two cases of pernicious anemia with high color index had comparatively high cell potassium. Possibly the concentration of hemoglobin determines the amount of potassium in the cells, since in all probability a good proportion of potassium is bound to hemoglobin.

Age may also be an influencing factor upon the red cell potassium levels. Twelve miscellaneous cases in which the patients were over fifty-five years old showed an average red cell potassium of 444 mg. per 100 c.c. as compared with 422 mg. per 100 c.c. in normal young adults. But the influence of age, as well as that of anemia and serum total base, on the red cell potassium level will require much further study before their importance can be properly estimated.

Serum potassium was found to be altered appreciably only in Bright's disease and in asthma. In the former disease, serum potassium was usually found to be high whenever there was marked nitrogenous retention. This rise took place often in the presence of very low red cell potassium concentrations, and suggested that in these cases there were factors preventing a rise in red cell potassium. The actual degree of rise in serum potassium in these cases was probably determined by the intake of potassium, for very high serum potassium values were found in cases that had been given potassium salts. These cases may be the ones that are more easily intoxicated by potassium medication.

In asthma, the high serum potassium and its lowering by epinephrine are in keeping with the findings in experimental anaphylaxis by numerous investigators.^{13, 14, 15} Whether there are any causal connections between the asthmatic symptoms and the level of serum potassium cannot be decided here.

SUMMARY

1. A new method for the estimation of whole blood potassium is described.
2. The partition of potassium between red cells and serum has been determined in 112 individuals.
3. In general, the levels of both serum and red cell potassium were constant both in health and disease. The normal serum potassium averaged 19.3 mg. per 100 c.c., and the red cell potassium 422.7 mg. per 100 c.c.
4. The most marked disturbances were found in Bright's disease.
5. The high serum potassium found in asthma was lowered by epinephrine.
6. Some possible relationship between red cell potassium concentration and serum total base, hemoglobin, and age are pointed out.

Most of the cases presented in this paper were patients in the Presbyterian Hospital, the Central Free Dispensary or Cook County Hospital.

THE SCHILLING DIFFERENTIAL BLOOD COUNT IN TROPICAL DISEASES*

A STUDY OF 710 CASES WITH SPECIAL REFERENCE TO MALARIA

PAULINE BEREGOFF, M.D., COLOMBIA, S. A.

WHILE the literature on the Schilling differential white blood cell count is extensive, few papers have been written of its value in tropical medicine. We thought it, therefore, worth while to report our findings of 710 cases of tropical diseases with special reference to malaria.

MATERIAL

1. Blood from 560 patients with malaria. These patients were divided into two groups, chronic and acute cases. Hemograms were studied during the different stages of the cycle, but as we found no particular change in the hemogram, only those taken during the febrile stage are charted. Hemograms were also studied during quinine therapy and after recovery.

2. Blood from 75 patients with severe secondary anemia due to intestinal parasites. These patients were divided into two groups: those who did not show intestinal ulcerations and those who presented marked intestinal pathology. Hemograms were taken on admission, during therapy, and before discharge.

3. Blood from 50 patients with leprosy, all males. These patients were divided into four groups as follows: Children with no open active lesions; children presenting lepromas in degeneration involving the bones; adults with no

*From the Department of Experimental Medicine of Santa Clara Hospital and the Departments of Pathology and Parasitology of the University of Cartagena.

active lesions; and adults with ulcerative lesions involving the bones. Hemograms were taken from patients who had not received any therapy; from patients beginning chaulmoogra oil therapy; and from those who were under treatment of chaulmoogra oil or its esters, for a considerable length of time and who presented marked improvement.

4. Blood from 15 patients who presented tropical ulcers of three years' duration. Hemograms were studied on admission, also during calcium therapy and after two months of calcium administration, when the patients showed marked improvement.

5. Blood from 15 patients presenting mycotic disease of the skin (actinomycosis, sporotrichosis, blastomycosis). Hemograms were studied soon after admission, during iodine and calcium therapy, and before leaving the hospital or clinic.

Most of the patients were hospital cases. Those who were not, were carefully studied at the clinic. All bloods were obtained not before two hours after a meal and when the patients were well rested.

Eighty per cent of the patients were of the colored race. Due to intestinal parasitic infection which was present in 100 per cent of the colored patients and in 70 per cent of the white, most of them presented a moderate anemia and a somewhat increased eosinophile and basophile count. The hemoglobin of these patients ranged between 72 per cent and 50 per cent (Sahli). None presented a higher hemoglobin than 72 per cent and seven patients showed a hemoglobin below 50 per cent.

The hemogram was recorded after a count of 100 cells in all malaria cases and after a count of 200 cells of the bloods of all the rest. An average was taken of each group and recorded.

INTERPRETATION OF THE HEMOGRAM

In the cases studied we have been able to correlate the degree of the shift in the hemogram with the extent of the infection and gravity of the patients' condition. Like Yaguda,² John,³ McDonald,⁴ Allen,⁵ and other investigators, we have found the Schilling differential count of great diagnostic and prognostic value. In malaria, especially of the pernicious type, serial hemograms present a valuable index in the administration of quinine therapy. In the chronic cases, after quinine intake, an immediate shift to the right with a neutrophile

TABLE I
THE SCHILLING HEMOGRAM

	W.H.C.	BASOPHILES	EOSINOPHILES	MYELOCYTES	JUVENILES	BANDS	SEGMENTS	LXAMPHIOCYTES	MONOCYTES	NEUTROPHILES
Standard	7,000	1	2	0	0	4	64	23	6	68
Regenerative	10,200	0	0	2	12	35	41	9	1	90
Degenerative	3,500	0	1	0	0	25	28	40	6	53

increase takes place. In the pernicious fevers, intravenous quinine therapy brings about a quicker response and change in the hemogram than oral or intramuscular therapy. The greater and severer the infection the greater the shift to the left in the hemogram. A shift to the right with an increased white blood cell count is almost always a good prognostic index. When the patient responds

TABLE II

FIFTY CASES OF SEVERE SECONDARY ANEMIA DUE TO INTESTINAL PARASITES PRESENTING NO INTESTINAL ULCERATIONS

STANDARD	W.B.C. 7,000	B. 1	E. 2	M. 0	J. 0	B. 4	S. 64	L. 23	M. 6	N. 68
Average of 50 cases	6,500	3	9	2	0	20	40	18	8	62
Average of the same cases after successful treatment by the Rivas Method for parasites, combined with intravenous therapy of iron, arsenic, and phosphorus	7,500	1	3	0	0	9	61	20	6	70

TABLE III

TWENTY-FIVE CASES OF SEVERE SECONDARY ANEMIA DUE TO INTESTINAL PARASITES AND PRESENTING INTESTINAL ULCERATIONS

STANDARD	W.B.C. 7,000	B. 1	E. 2	M. 0	J. 0	B. 4	S. 64	L. 23	M. 6	N. 68
Average of 25 cases	11,000	2	8	1	2	21	50	12	4	74

In the above cases, the degree of the shift kept on changing as the treatment went on, and it was an excellent index in the prognosis. A shift to the right with an increase in segments, decrease in bands, and somewhat increased eosinophile count was noticed when the ulcerations began to heal. The eosinophiles and neutrophiles reached the normal level when recovery was attained. One of the patients died of intestinal perforation due to amebic ulcers, and the following hemograms were presented before death:

Two days before death	17,000	3	9	4	8	32	34	7	3	78
One day before death	8,000	3	9	4	12	40	23	7	3	78

TABLE VI
FIFTY CASES OF LEPROSY, 15 CHILDREN AND 35 ADULTS, ALL MALES

STANDARD	W.B.C. 7,000	B. 1	E. 2	M. 0	J. 0	B. 4	S. 64	L. 23	M. 6	N. 68
Average of 10 children; ages 7 to 14. No ulcerative lesions. Lymph positive for B. lepra	8,000	1	8	0	0	8	34	40	9	42
Average of 5 children, presenting lepromas in degeneration, involving bones of feet and hands	12,000	2	9	1	4	12	45	20	7	62
Average of 15 untreated lepra adults; no active lesions	7,500	1	5	0	0	10	56	28	8	66
These patients after the first few injections of chaulmoogra oil, presented the following hemogram	10,000	1	7	0	0	10	58	18	7	68
Average of 20 adult lepers, with active lesions involving bones of feet and hands	12,000	1	9	1	8	18	40	20	4	66
Chaulmoogra therapy in these patients, at the beginning raises the W.B.C., increases the neutrophile count and segments, and diminishes the juveniles. Hemogram after 5 days' treatment. When the patients presented marked improvement under therapy the hemogram changes toward a slight right shift	14,000	1	9	1	3	12	56	14	4	72
Average of 15 treated patients, who presented repeated negative findings in the lymph and nasal mucus during a two months' period	7,000	1	6	0	0	7	60	20	6	74

TABLE VII
FIFTEEN CASES OF TROPICAL ULCERS

STANDARD	W.B.C. 7,000	B. 1	E. 2	M. 0	J. 0	B. 4	S. 64	L. 23	M. 6	N. 68
Average of 15 cases on admission	6,300	3	7	0	4	15	46	18	7	65
After 3 intravenous calcium gluconate (Sandoz) injections, during three days, sloughing of the ulcer became noticeable and the following hemogram was recorded	9,000	2	8	0	2	15	54	16	4	70
After 24 intravenous injections of calcium (Sandoz) 10 c.c., sloughing disappeared, granulation tissue formed with marked improvement in healing. The following hemogram (average) was recorded	8,000	1	5	0	0	8	64	17	5	72

a diminished lymphocyte count, shift to left with low white blood cell count is almost always an unfavorable prognostic index.

In the anemias of parasitic origin, we found a basophilia and eosinophilia with an increase in band forms. Improvement of the patient is correlated with a decrease in eosinophiles and basophiles as well as bands with an increase in lymphocytes and segmented neutrophils. In the patients who presented severe ulcerative intestinal lesions, the disappearance of neutrophilia with an increase in lymphocytes and monocytes was always an indication of improvement, while a decrease of the white blood cell count and lymphocytes with a marked left shift was always of poor prognosis.

In mycosis, we found a slight basophilia and eosinophilia with a slight left shift in the hemogram. The patients who responded rapidly to iodine and calcium therapy showed a rapid shift to the right. Often the first few injections bring about a change in the hemogram, but should the therapy be discontinued before healing is complete, a shift to the left takes place. Recovery is indicated by a persistent slight shift to the right with a slight elevation of lymphocytes and monocytes.

In the cases of tropical ulcer, the hemograms present practically the same form as those seen in mycotic lesions.

In leprosy, we find hemograms almost identical with those found in tuberculosis. Where active lesions are present, a shift to the left is almost always present. In the treatment of the patients, the hemogram is a good indication of the response to therapy.

The progress of a patient may be very accurately followed up by frequently repeated hemograms. Like Harter and Lyons, Reznikoff,⁷ Baum⁸ and others, we consider the Shilling differential of greater value as a diagnostic and prognostic index than the Arneith or Ehrlich formula, and most readily adaptable as a routine method.

SUMMARY AND CONCLUSIONS

1. A study of the Schilling hemogram in 710 cases of tropical diseases is presented. These cases comprise 560 patients with malaria, 75 patients with severe anemia due to intestinal parasitic infestation, 50 leprosy patients, 15 cases of tropical ulcers, and 15 of mycotic disease of the skin.

2. Hemograms are reported before beginning therapy, during and at conclusion of therapy.

LABORATORY METHODS

A RAPID COLORIMETRIC METHOD FOR MULTIPLE DETERMINATIONS OF URIC ACID*

GEOFFREY KEIGHLEY, B.A., AND HENRY BORSOOK, PH.D., PASADENA, CALIF.

DETERMINATION OF URIC ACID

IN A STUDY of protein metabolism in which we are engaged, a large number of urinary uric acid determinations were called for. It was clear, at the outset, that the employment of a colorimeter would be laborious and time-consuming, chiefly because of the necessity of preparing a new standard for every sample to be analyzed. This difficulty was avoided by substituting a spectrophotometer for a colorimeter for measuring the depth of color.

The chemical reagents employed were those of Morris and Macleod.¹ The technic was modified in adapting it for use with a spectrophotometer, because in the method as it is ordinarily used there is a continuous intensification of color in both the standard and in the unknown. This is shown in Table I.

It was necessary to alter the conditions so that a maximum color, which does not change further on standing, is obtained before any readings are taken. The modification is the incubation of the uric acid together with the arsenotungstic-cyanide reagent in a total volume of 36 c.c. at 37° C. for thirty-five minutes. The solution is then cooled and made up to 50 c.c. Readings may then be taken at any time during an interval of one and one-half hours (Table III).

The advantage gained in this modification is that a large number of solutions containing unknown amounts of uric acid may be made up together. The depth of color obtained in each is then measured in the spectrophotometer and interpreted in terms of amounts of uric acid by means of an empirical curve constructed from the color intensities given by known quantities of uric acid. Having once obtained the empirical curve, it is unnecessary to make up standard solutions again for comparison with the unknown. Occasionally one standard solution is prepared to check the constancy of the reagents.

EXPERIMENTAL

The reagents and general procedure employed (with the modifications described below) were those given by Morris and Macleod.¹ The standard uric acid solution was prepared by the method of Benedict and Hitchcock.²

*From the William G. Kerckhoff Laboratories of the Biological Sciences, California Institute of Technology.

Received for Publication, April 10, 1933.

A brief presentation of the principles underlying the use of a spectrophotometer for the measurement of color is given by Clark.³ We have employed a König-Martens type of instrument, with an attachment so that the angle at which the Nicol prism was set for color match when water was in train was 45° . The equation connecting differences in concentration of absorbing substance with differences in color intensity is

$$\frac{C_1}{C_2} = \frac{\log \tan^2 \theta_1}{\log \tan^2 \theta_2}$$

where θ_1 and θ_2 are the angular readings on the instrument for color match with concentrations C_1 and C_2 respectively.

One of the advantages of a spectrophotometer over a colorimeter is that independent check readings may be made at any number of desired wave lengths; any one corresponds to a reading with a colorimeter.

The absorption cell used was 20.8 mm. wide, and was covered with a glass slide while measurements were being made.

In Table I are shown the differences in the rates of development of color with three different concentrations of uric acid, when the unmodified procedure of Morris and Macleod is followed. Columns five and six show that a good proportionality exists in the first ten minutes between depth of color developed and amount of uric acid. The table also shows the necessity when a colorimeter

60	0.97	1.79	2.46	0.54	1.39

is to be used with this technic of preparing the standard and the unknown solution at the same time.

The influence of the dilution of the reaction mixture on the intensity of color developed was not sufficiently emphasized by Morris and Macleod. Table II shows that this is an important factor; and that this must be kept constant if constant results are to be obtained. The uric acid and reagents, made up with water to the total volumes indicated in Table II were incubated at 37°C . for thirty-five minutes. They were then cooled, diluted to 50 c.c., and the intensity of color developed was measured immediately after.

It was found that if the reagents and the uric acid are kept for thirty-five minutes at 37° C., there is only a negligible further development of color after cooling to room temperature and dilution to 50 c.c. A typical result is given in Table III.

TABLE II

10	2.15	0.219
23	2.17	0.224
30	2.17	0.224
60	2.19	0.227
90	2.23	0.232

The following was the final procedure employed: One cubic centimeter of diluted urine, usually the original urine diluted three times, was pipetted into a 50 c.c. centrifuge tube. Thirty-eight cubic centimeters distilled water, measured with a graduate, 1 c.c. of 2.5 per cent zinc chloride, and 1 c.c. of 10 per cent sodium carbonate were then added. The solution was stirred and centrifuged. The supernatant solution was then poured off and the precipitate dissolved with 4 drops of 10 per cent HCl. This was then transferred with 30 c.c. of distilled water to a 50 c.c. volumetric flask. Five cubic centimeters of 10 per cent sodium cyanide and 1 c.c. of the arseno-18-tungstic acid solution were then added. The flask was quickly swirled, and then set away, stoppered, in a water-bath at 37° C. After thirty-five minutes it was cooled; the volume made up to 50 c.c.; and the intensity of color developed then read with the spectrophotometer.

With this procedure the data shown in Tables IV and V were obtained.

From the data in Table IV empirical calibration curves were constructed; because with the modified technic, the value of the proportionality constant relating intensity of color to the amount of uric acid is not 1. Table V gives the ratios computed from the data in Table III of the color intensity developed by different amounts of uric acid to that given by 0.2 mg. which was taken as a standard. The ratios at $\mu\mu$ 515 may be employed as correction factors when a colorimeter is used with the above procedure for development of the color; though it would be safer to construct a calibration curve.

TABLE IV

ABSORPTION AT VARIOUS WAVE LENGTHS OF SOLUTIONS CONTAINING DIFFERENT AMOUNTS OF URIC ACID

AMOUNT OF URIC ACID MG.	ABSORPTION = $\log \tan^2 \theta$ FOR VARIOUS WAVE LENGTHS IN $\mu\mu$									
	515.5	526	537	549	561.5	575	590	607	627	670
0.05	0.38	0.41	0.44	0.48	0.53	0.58	0.63	0.71	0.77	0.82
0.10	0.63	0.68	0.74	0.82	0.90	0.99	1.10	1.21	1.34	1.45
0.15	0.81	0.89	0.98	1.08	1.20	1.33	1.48	1.64	1.81	1.97
0.20	0.97	1.08	1.19	1.31	1.46	1.62	1.80	2.00	2.19	2.38
0.25	1.14	1.26	1.39	1.53	1.72	1.91	2.12	2.34	2.59	2.79
0.30	1.33	1.47	1.61	1.79	2.00	2.23	2.48	2.76	3.06	3.29
0.35					2.22	2.47	2.76	3.08	3.36	
0.40	1.56	1.73	1.91	2.12	2.36	2.65	2.91	3.29	3.52	4.04

When only two or three urinary uric acid determinations are to be made, the unmodified procedure of Macleod and Morris is probably quicker. But, as in our case, when there is a large number of analyses the modified technic described above affords a great saving in time and labor, whether a colorimeter or spectrophotometer is used; since all the unknowns and only one standard solution may be made up together.

TABLE VI

VALUES OBTAINED AT DIFFERENT WAVE LENGTHS IN URINARY URIC ACID DETERMINATIONS SHOWING THAT THE ABSORPTION SPECTRUM IS THE SAME FOR URINE AS FOR PURE URIC ACID

WAVE LENGTH $\mu\mu$	SAMPLE 1 MG.	SAMPLE 2 MG.	SAMPLE 3 MG.
627	0.108	0.194	0.295
607	0.108	0.194	0.297
590	0.108	0.196	0.298
575	0.108	0.195	0.299
561.5	0.109	0.195	0.297

Because approximately monochromatic light is used in the spectrophotometric readings it was necessary to know whether or not the same absorption spectrum is obtained when the uric acid is precipitated from urine as with pure uric acid; i.e., whether or not the contaminants in the zinc urate precipitate affect the color obtained. Table VI shows that the absorption spectra given by pure uric acid

and by uric acid precipitated from urine are identical. Had there been any difference the values of the different wave lengths would have exhibited a systematic variation. The agreement in the three sets of determinations in Table VI is typical of the results in more than one hundred analyses.

SUMMARY

A modification of the technic of Morris and Macleod for the determination of uric acid is described which permits much more rapid analysis of a large number of samples. If a calibration curve has been constructed previously, this technic obviates the necessity of preparing a standard solution for comparison when a spectrophotometer is used; with a colorimeter only one standard need be prepared.

STUDIES OF THE PHYSIOLOGIC AND PATHOLOGIC CHEMISTRY OF THE SKIN*

PRELIMINARY REPORT

ABRAHAM RUDY, M.D., BOSTON, MASS.

MICROMETHOD FOR THE DETERMINATION OF THE SUGAR CONTENT IN THE SKIN

UNTIL recently the only functions of the skin generally considered were its protective, heat regulating, secretory, and sensory functions. There was little knowledge of its physiologic and pathologic chemistry. Wohlgemuth and his coworkers,¹ Klopstock and Buschke,² and Meleser³ were the first to demonstrate in the skin enzymes like amylase, diastase, tryptase, lipase, etc., in as high concentration as they are found in the liver. They have shown that the skin has its own specific metabolism of carbohydrate, protein, and fat, and other substances. Pillsbury⁴ found that lactic acid, which is an important product of carbohydrate metabolism, is normally present in the skin. Studies of the normal and pathologic metabolism of the skin promise to be of utmost importance in diseases of the skin as well as in other pathologic conditions. Diseases of the skin should not only be studied now from the etiologic and histologic standpoint, but consideration should also be given to the specific metabolism of the skin which may be disturbed while the metabolism of the other organs or the blood chemistry may be found to be normal.

*From the Department of Pathology and Medical Clinic, Beth Israel Hospital.
Received for publication, May 11, 1933.

The work done on the enzymes has been carried out on cadavers and a few amputated limbs. Gansslen⁵ and Wohlgemuth and Scherk⁶ undertook a chemical study of the content of artificially produced blisters in man, in the belief that it would represent the chemistry of the skin *in vivo*. Urbach,⁷ who was the first to study the chemistry of the human skin *in vivo*, has demonstrated, however, a difference in the chemical values obtained from the blisters and from the skin. Together with Fantl⁸ he developed a micromethod for the determination of the sugar content in the skin. With Sieher⁹ he carried out studies on the sugar content of the skin *in vivo* under normal and pathologic conditions. They found that the fasting sugar of the human skin is normally lower than that of the blood, and that the sugar in the skin increases parallel with the sugar in the blood. In some skin diseases, as well as in latent diabetes, they found that after the ingestion of 100 gm. of glucose, the sugar in the skin increased above normal, although the blood sugar rise was within normal limits. In other cases, which according to them belong to the sympathetic endocrine group, the blood sugar curve reaches a very high level within an hour after the glucose ingestion, and rapidly falls with no abnormal increase in the height of the skin sugar curve. I found that the sugar content in normal human skin after intravenous glucose injection, and in uncontrolled diabetics is markedly elevated above the normal level. In my experiments with Abrams¹⁰ on rabbits we confirmed the findings of Folin, Trimble and Newman¹¹ that the skin sugar rises rapidly with intravenous injection of glucose and drops with the fall of the blood sugar. In addition we found that the rise in the skin sugar of the rabbit occurs as soon as ten to twenty seconds following the intravenous injection of glucose. The glucose apparently spreads rapidly by diffusion through the blood and lymph systems.

It is evident that the studies of the physiologic and pathologic chemistry of the skin should be carried out only on skin samples which represent the skin *in vivo*, as is true in the chemistry of the blood, and in order that these studies may be of practical value, micromethods should be applied. The sample of skin which is used for chemical analysis should be easily removed without any harm or great discomfort to the patient, although without anesthesia.

Urbach and Fantl's method calls for an electric Kromayer puncher and the application of two stitches or clips. The weight of the skin removed varies between 100 and 160 mg. The sugar determination on the extract is carried out by Hagedorn-Jensen method. The method proposed below is an adaptation of Folin's¹² micromethod for sugar in the blood, which is more commonly used in this country. The removal of the skin specimen and the determination of its weight is also carried out in a somewhat different manner. The test can be performed on very small pieces of skin, especially when a high sugar value is expected. It is best, however, when the skin specimen weighs in the neighborhood of 50 mg.

REMOVAL OF THE SKIN AND PROCEDURE OF THE TEST

Our aim is to obtain the skin in as normal a condition as possible. For this reason only healthy appearing skin should be removed and no local anesthetic should be used. The skin does not represent an homogenous tissue in all parts

of the body, and therefore, for the purpose of comparison, the same regions should be used in comparing different individuals, or parallel body surfaces in the same individual. I use the costovertebral region. It is free from hair, and does not require shaving. In addition, the patient is less conscious of the procedure.

The skin is cleaned with soap and water and then with alcohol about one or two hours, or if possible twelve hours before, and covered with a dry sterile dressing. The epidermis and corium of the skin is picked up with a small dry toothed forceps of rustless steel, and a piece about the size of one-quarter to one-half square centimeter is cut off quickly with a sharp, dry, sterile scalpel. The scalpel should cut through the epidermis and corium, and not touch the subcutaneous fat, if possible. There is no bleeding until after the specimen is removed. The wound is swabbed with mercurchrome and covered with a small tight dressing. The specimen is placed with the corium up into a covered Petri dish, taken immediately to the laboratory, minced,* and then weighed. In case the skin has some fat attached, which can be recognized by its yellow color, it should be removed with scissors before weighing. This is important because the sugar content of the fat is very low, and thus will lower the results of the skin sugar tests. The weight of the skin sample is determined on an analytical scale. Bang's scale is most convenient for this purpose. When the regular analytical scale is used, the skin should be weighed on a watch glass covered with another to prevent evaporation. The weight of the pair of watch glasses with and without the skin specimen is determined. The difference between the two weights gives the weight of the skin. Since the specimen is very small its weight should be recorded accurately to the tenth of a milligram. After the weight is taken, the skin is transferred into a 15 c.c. centrifuge tube containing 10 c.c. of dilute tungstic acid solution, as is used in Folin's¹² micromethod for sugar. When the weight of the skin sample is below 50 mg. and the sugar content is expected to be low, only 5 c.c. of the tungstic acid solution should be used. The skin is well stirred with a glass rod and the tube is then placed in a cool place, preferably a refrigerator, for twenty-four hours. The extraction is often completed in four hours.

From this point the test is carried out as described by Folin¹² in his improved micromethod for the determination of sugar in laked blood. For greater convenience I am giving here the full procedure.

Transfer 4 c.c. of the skin extract to a test tube graduated (with a ring all around) at 12½ and 25 c.c. Make two standards, one containing 4 c.c. of the standard sugar solution, and the other containing 2 c.c. of the standard sugar solution and 2 c.c. of distilled water in two similar tubes. To each tube add 1 c.c. of the 0.4 per cent potassium ferrieyanide solution and 1 c.c. of the cyanide carbonate solution. When the sugar content of the skin is expected to be high, 2 c.c. of the potassium ferrieyanide should be used. Heat in boiling water-bath for eight minutes, and cool in running water for from one to two minutes. Add 5 c.c. of the ferric iron solution and mix. Let stand for from one to two minutes, and then dilute with water to the 25 c.c. mark and mix. In case the color of the sample is light, dilute it

*Only nonrustable scissors and forceps should be used, since the iron of the instruments may contaminate the test.

only to 12½ c.c. and the standard to 25 c.c. In case a little foam is obscuring the surface of the solution, a couple of drops of ethyl alcohol may be added before diluting with water. For the colorimetric reading it is advisable to use Malumros' acid picrate light filter.

CALCULATION

The calculation differs from that in Folin's¹² micromethod, in that, there is a correction needed for the weight of the skin and for the modified dilutions.

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \frac{100}{\text{weight of skin in mg.}} \times \text{change in dilution} \times 100 = \frac{\text{mg. sugar per}}{100 \text{ gm. skin.}}$$

A sufficient number of tests have been done by the above method to indicate its accuracy.

First, specimens taken from cadavers and from amputated limbs were studied. The skin was usually removed by the same technic as with in vivo studies. On some occasions a larger piece of skin was taken and divided into a number of smaller fractions. In Table I are given figures showing the results obtained on several specimens of skin removed from adjacent parts of the same body or amputated limb. The skin of the cadaver, as a rule, was found to have a low sugar content unless uncontrolled diabetes was present or intravenous glucose was used before death. Most of the sugar values obtained from skin samples of the same part of the body agree within 10 per cent. In Table II

are given the results obtained on in vivo removed specimens of skin compared with the results of the capillary blood sugar determined by the same method. The specimens in this table were taken from patients on the skin service about two to three hours after breakfast, except in one case of diabetic coma. On some occasions the skin specimen was divided in two pieces. Each piece was weighed, and its sugar content separately determined with quite close checks. The skin sugar in most instances was somewhat higher than the capillary blood sugar. Urbach and Sieher⁹ found that the fasting skin sugar is lower than the fasting venous blood sugar. I suppose that the higher skin sugar figures I have obtained may be explained by the fact that the skin samples were mainly taken from two to three hours after breakfast and that the return of the skin

sugar to normal is slower than that of the blood sugar. Urbach and Sicher also claim that the skin sugar is elevated in some skin diseases and that diabetes mellitus can be discovered with the aid of a skin sugar tolerance test earlier than with the blood sugar tolerance test. For practical purposes, however, I believe that a single skin sugar determination carried out from about one to three hours after a high carbohydrate meal should be sufficient. Folin and Swed-

berg's¹³ micromethods for the determination of nonprotein nitrogen and uric acid in unlaked blood can be adapted for the determination of the same in the skin. Experiments are now being carried out to determine the smallest size of skin sample as well as the dilutions necessary for these determinations.

SUMMARY

Attention is called to the importance of the studies of the physiologic and pathologic chemistry of the skin.

A micromethod for the determination of the sugar content of the skin in vivo is described. Similar methods for the determination of the nonprotein nitrogen and uric acid content of the skin are suggested.

The chemistry of the skin may play an important rôle in the studies of some skin diseases and metabolic disorders.

I wish to thank Dr. Jacob Swartz for his helpful suggestions and kind permission to use the cases from the Skin Service.

A DIRECT NESSLERIZATION METHOD FOR UREA NITROGEN IN BLOOD WHERE COMMERCIAL UREASE IS EMPLOYED*

CLARA S. SHAPIRO, M.A., NEW YORK, N. Y.

IN RECENT years the direct nesslerization method for urea nitrogen has been coming more and more into general use. The Karr¹ modification of it has been accepted by some hospitals and private laboratories as a regular routine procedure in place of the more cumbersome, although possibly more accurate, aeration method. In view of the increasing use of the direct nesslerization method, it seems desirable to have it further improved in order to obtain more reliable results.

The following changes seem to be especially desirable:

1. To avoid or delay the formation of turbidity on nesslerization so that an accurate reading can be taken.

2. To modify it in such a way that commercial urease can be used instead of a specially prepared urease extract. The urease manufactured by a reliable company gives uniformly accurate results, while the preparation of urease extract at a hospital, besides being time consuming, frequently results in products of varying potency. Such urease extract is sometimes a source of considerable error in the urea determination. The preparation of these extracts requires careful technic and accurate checking, which is not always possible, especially in small laboratories.

*From the Laboratory of the Life Extension Institute.
Received for publication, May 19, 1933.

3. To obtain a color on nesslerization which will match an ammonium sulphate standard and thus eliminate the necessity for a urea standard as employed in Karr's method.

Ammonium sulphate solutions keep indefinitely and give dependable results. Urea standards have to be renewed every month with the added disadvantage that a preservative, such as toluene, may have an undesirable effect on the color of the nesslerized urea standard.

The method here described represents an attempt to answer the above-mentioned requirements. The principle consists in incubating the Folin-Wu blood filtrate with ordinary commercial powdered urease which is later removed from solution by precipitation with an additional amount of tungstic acid; the flocculent precipitate formed is filtered off through ordinary filter paper. The resulting water-clear filtrate is then nesslerized and compared against a nesslerized standard ammonium sulphate solution.

METHOD

Reagents.—

1. *Standard Ammonium Sulphate Stock Solution*: Dissolve 0.4716 gm. of C. P. ammonium sulphate in a little water and make up to one liter; 10 c.c. of this solution contains 1 mg. of nitrogen.

2. *Nessler's Solution* (2): Introduce into a large beaker or Erlenmeyer flask, about 500 c.c. of water, add 100 gm. of C. P. sodium hydroxide. Place the flask in a pan of cold water to prevent the development of heat. Let stand until all dissolves and the solution is cool. In the meantime, introduce through a paper cone into a dry 1,000 c.c. volumetric flask, 100 gm. U.S.P. mercuric iodide (Hg_2I_2), 70 gm. C.P. potassium iodide and about 400 c.c. of distilled water. Rotate the flask to dissolve. Occasionally a few grains of mercuric iodide will remain undissolved, which does not interfere. When all has dissolved, add the sodium hydroxide solution slowly with constant rotation of the flask, and make up to 1 liter with water. Mix and transfer to a bottle with a rubber stopper. Let stand overnight, preferably in an incubator at 37 or 38° C. In the morning, a fine brown precipitate will be found on the bottom of the bottle. The supernatant fluid can be siphoned off or filtered through cotton.

This stock solution keeps indefinitely. *It has to be diluted 1:5 just before use.*

3. $\frac{1}{12}$ Normal Sulphuric Acid: It is prepared from $\frac{2}{3}$ normal H_2SO_4 by diluting the latter 8 times.

Procedure.—Prepare the Folin-Wu filtrate as usual, or, if desired, the following simplified technic can be used, which invariably gives excellent results:

For each cubic centimeter of oxalated blood, add 8 c.c. of $\frac{1}{12}$ normal H_2SO_4 , and 1 c.c. of 10 per cent Na_2WO_4 solution. Rotate the flask 2 or 3 times. Filter at once. The filtrate should be water-clear. Into an ordinary test tube of about 30 c.c. capacity, pipette 10 c.c. of Folin-Wu filtrate. Incubate with approximately 0.1 gm. Urease powder (Squibb) for fifteen minutes at 50° C. To the incubated filtrate, add 1 c.c. of distilled water, 8 c.c. of $\frac{1}{12}$ normal H_2SO_4 (or 1 c.c. of $\frac{2}{3}$ normal H_2SO_4 and 7 c.c. H_2O) and 1 c.c. of a 10 per cent solution of sodium tungstate. The total volume is 20 c.c. Mix several times by inversion. Filter off the flocculent, white precipitate through ordinary filter paper. The filtrate should be water-clear.

Into a 100 c.c. graduated cylinder, pipette 10 c.c. of this final filtrate (equivalent to 0.5 c.c. of blood). Add 3 c.c. of distilled water and 2 c.c. of dilute Nessler's solution, freshly prepared from the stock solution. Adjust to 15 c.c. mark. Mix by inversion. Compare *at once* against standard ammonium sulphate solution, which is prepared as follows: 5 c.c. of stock ammonium sulphate solution (equivalent to 0.5 mg. nitrogen) are diluted with water treated with 20 c.c. of dilute Nessler's solution and made up to 100 c.c. in a volumetric flask.

If the color of the unknown is darker than that of the standard, add more of the Nessler's solution until no more increase in color is observed. (In the case of very high urea content, 20 or 25 c.c. of Nessler's solution are required.) Dilute immediately with water to desired volume until the color approaches that of the standard. Mix and compare at once. The nesslerized solution should be perfectly clear and should remain so for several minutes. The higher the nitrogen content of solution the longer it will stay clear (three minutes to one hour). Smoke and fumes in the laboratory have been observed to accelerate the formation of turbidity.

Calculation:

$$\frac{\text{Standard Reading}}{\text{Unknown Reading}} \times \frac{\text{Unknown Dilution}}{\text{Standard Dilution}} \times \frac{\frac{1}{2} \text{ mg. N in Standard}}{\times 2 \times 100} = \frac{\text{mg. Urea N in 100 c.c. of blood}}{\text{Simplified this becomes (Standard at 20)}}$$

$$\frac{20}{\text{Unknown Reading}} \times \text{Unknown Dilution} = \text{mg. Urea N in 100 c.c. of blood}$$

RESULTS

The method described was tested out on a number of bloods as well as on control solutions. The latter was done in order to ascertain that commercial urease after being removed from solution does not leave behind some substances which will affect the accuracy of the method. Standard ammonium sulphate solutions of concentrations, from 10 to 200 mg. nitrogen per 100 c.c., served as controls. They were treated exactly as if they were bloods, namely, 1 c.c. of such solution was diluted with 10 c.c. of water, mixed with 0.1 gm. of solid urease and the latter was precipitated by addition of 8 c.c. of $\frac{1}{12}$ normal sulphuric acid and 1 c.c. of a 10 per cent solution of sodium tungstate solution as described above. The results are given in Table II.

As can be seen from the table the recovery of the nitrogen is quite good, the error not exceeding ± 3 per cent, which is the theoretical error of the direct nesslerization procedure. (The error of the colorimeter reading = 1-1.5 per cent under routine conditions. The combined error of pipetting, dilution, etc., is at least 1-1.5 per cent. The total is equal to ± 3 per cent.)

This method was next tested on a number of normal bloods, to some of which known amounts of a standard urea solution were added. The results obtained were checked against the aeration procedure. Also a number of pathologic bloods was obtained from the Coney Island Hospital, New York City, and the urea determined by the same method. The results were compared with those of the Coney Island Hospital laboratory, where Karr's direct method is used exclusively.

solution which was equivalent to 15 mg. nitrogen in 100 c.c. It was treated exactly like the blood specimens. A urea control equivalent to 14 mg. of N in 100 c.c. was also used. This was incubated with Squibb's urease and aerated along with the bloods. The nitrogen recovery in the case of both controls was from 97 per cent to 103 per cent as Table I shows.

The data on blood determinations are given in Table III. The agreement between the method proposed and the aeration method, with a few exceptions, is under 6 per cent, which is within the theoretical tolerances.

DETAILS OF METHOD

In an attempt to prevent completely the formation of turbidity a number of other urease precipitants were tried; these included *95 per cent alcohol* of which 10 c.c. were added to 10 c.c. of Folin-Wu filtrate giving a final concentration of 50 per cent alcohol; also 5 c.c. were added giving a final concentration of 30 per cent alcohol; *trichloroacetic acid*, 300 mg.; *HNO₃ concentrated*, 1 c.c.; *HCl concentrated*, 1 c.c.; *H₂SO₄*, 10 per cent solution, 0.2 c.c.; *sulphosalicylic acid*, 3 per cent solution; *NaOH*; *1 normal*, 1 c.c.; *Na₂CO₃* saturated solution, 1.5 c.c.; *BaCl₂*, dilute solutions, varying amounts.

All of these substances except *HCl*, *H₂SO₄*, 10 per cent, and alcohol 30 per cent remove the urease completely, leaving a water-clear filtrate. On nesslerizing the latter, however, a greenish tinge and immediate turbidity were produced with alcohol 50 per cent and 30 per cent, *BaCl₂*, trichloroacetic acid, *NaOH* and *Na₂CO₃*. The 10 per cent sulphuric acid, sodium hydroxide, and sodium carbonate in the concentrations used, had a bleaching effect on color. Sulphosalicylic acid, *HCl* concentrated and *HNO₃* concentrated, prevent the formation of color altogether. It follows that tungstic acid is the best precipitant of commercial urease among those tried, because it allows a fairly stable color development on nesslerization. An attempt was made to reduce the amount of tungstic acid but was found impossible because of incomplete precipitation of urease.

Commercial urease appears to be more or less completely precipitated by a sufficient quantity of tungstic acid. At least the resulting filtrate is water-clear and on addition of another portion of tungstic acid not a trace of precipitate appears. The removal of the urease from solution causes a decided improvement in the color development on nesslerization. Although the formation of turbidity is not entirely avoided, it is delayed sufficiently to enable the technician to take an accurate reading. The nesslerized solution is obtained perfectly clear and remains so for a period of time varying from three minutes to one hour depending on the concentration of urea nitrogen. It has a good orange color and can be easily compared against an ammonium sulphate standard.

The greenish tinge is entirely absent from bloods of higher urea content. These bloods give a perfectly good match. The normal bloods, from 10 to 20 mg. per 100 c.c., do appear slightly greenish in the colorimeter, but can still be matched against the standard, the deviation from aeration procedure not exceeding 6 or 7 per cent.

In contrast to Karr's procedure, the method here proposed gives quite stable color in specimens of high urea content. Turbidity never develops immediately after addition of Nessler's solution. The color is good and perfectly clear for from about fifteen minutes to one hour. The stability of color decreases as the nitrogen content approaches the normal range, as Table IV shows.

TABLE IV
PERIODS DURING WHICH NESSLERIZED SOLUTIONS REMAIN CLEAR

N. PER 100 C.C.	DURATION OF CLEAR NESSLER'S SOLUTION
mg. 100-200	20 min. to 1 hour
50-100	10 min. to 20 min.
30- 50	5 min. to 10 min.
10- 30	3 min. to 5 min.

It is therefore advisable to nesslerize each specimen separately just before reading.

ADDENDA

While these experiments were in progress, an excellent direct nesslerization procedure was published by Dr. W. F. Taylor and Dr. W. M. Blair of Texas.⁴ Their method was tried out in this laboratory and was found to give good results, especially with bloods of high nitrogen content.

The nesslerized solutions in this method remain perfectly clear for about an hour or longer even in solutions of normal urea content. The match against standard ammonium sulphate is good in the case of more concentrated solutions. As to the normal bloods, they appear greenish in the colorimeter and are rather difficult to match when the standard is set at 20 mm. In our hands the error rose to about 20 or 30 per cent. Shifting the standard to 15 mm. reduces the difference in tinge between the unknown and the standard, which results in better agreement with the suction method. The results are given in Table V.

COMMENT

Since turbidity formation is completely obviated in the Taylor and Blair method, it might appear unnecessary to suggest another procedure. It was decided, however, to complete these experiments for the following reason:

1. The large amount of blood (5 c.c.) required in the method of Taylor and Blair makes it inconvenient to use in some cases especially in emergencies.
2. The special urease required for this method again calls for well-trained workers, a well-equipped laboratory, and additional time.
3. The method here presented can be completed in about thirty or thirty-five minutes and requires no special reagents. Because of its speed and simplicity it may be of use in emergency cases. It is believed to give more reliable results than Karr's procedure, because the nesslerized solution is more stable. It may, therefore, replace the latter where it is accepted as a routine procedure. This method is not intended, however, to replace the standard aeration procedure since the formation of turbidity is merely delayed but not completely obviated.

SUMMARY

A direct nesslerization procedure is proposed in which commercial urease is employed. The urease is removed from solution before nesslerization, and the color of the nesslerized solution is fairly stable so that a good reading can be taken. The stability of color increases with increased concentration of urea nitrogen in blood.

A number of urease precipitants were tried out in addition to tungstic acid. They gave, however, inferior results.

The Taylor and Blair direct method was tested and found to give satisfactory results in specimens of high urea content.

I wish to express my deepest thanks to Dr. James J. Short, Director of Laboratories at the Life Extension Institute, for permission to carry out these experiments and for numerous valuable suggestions.

I also wish to thank Dr. Harold Fink and Mr. Singer of the Coney Island Hospital for supplying me with pathologic bloods from the laboratory of the hospital and for giving me the results of their analyses.

A NEW METHOD FOR THE PRODUCTION OF ANTISHEEP HEMOLYSIN*

MARGARET BEATTIE, A.B., GR.P.H., BERKELEY, CALIF.

DURING the past ten years various methods for the production of agglutinating and hemolytic antisera have been tested in the teaching laboratory of the Department of Hygiene. Each year student workers have produced antisera by intravenous, subcutaneous, and intraperitoneal inoculations of antigens prepared in different ways but rarely have these antisera been of high titer. This has been particularly true in case of hemolysin for use in the Kolmer standard Wassermann test. Tuft, Yagle and Rogers¹ having shown that intracutaneous injection of typhoid vaccines produced the most satisfactory immunologic response, it was decided to employ this route for the administration of red blood cells or serum as suggested by Stafseth.²

Two rabbits received intracutaneous inoculations of sheep serum and two received sheep red blood cells. The serum from none of these animals produced hemolysis to any appreciable degree. One of the rabbits which had received sheep cells was then given four inoculations of cells intravenously and the other six additional intracutaneous injections of cells. Neither responded by any increase of hemolytic power. The two rabbits which had received sheep serum were given three intravenous inoculations of sheep cells five days after the last intracutaneous inoculation of sheep serum, and both produced an unusually powerful hemolysin.

In order to demonstrate whether this result was accidental, 16 rabbits were inoculated as follows: 5 intracutaneous injections of sheep serum were given at forty-eight-hour intervals, the initial dose being 0.5 c.c. and the final 2.5 c.c.; after four days three intravenous injections of 1.0 c.c. of a 10 per cent suspension of sheep red blood cells were given at forty-eight-hour intervals. Eleven other rabbits received egg albumen in place of the sheep serum in order to determine whether or not a nonspecific protein stimulation would be as effective. None of the 11 produced serum which was hemolytic in a dilution above 1-8,000 and only two reacted so actively.

Of the 16 rabbits 3 died before the last inoculation of cells was given, 2 before any cell inoculations, and one after two serum inoculations. All of these animals were emaciated and had severe diarrhea. On autopsy they showed

Aided by a grant from the Board of Research of the University.

extensive fibrosis of the subcutaneous tissues in the thoracic or abdominal regions. There were no significant lesions at the site of the serum inoculations and no visceral lesions. It was suggested that this was a type of anaphylactic reaction.

Of the 10 animals which survived the inoculations 7 had diarrhea and subcutaneous abscesses ventrally on the same side as the serum inoculation site. These animals were profoundly ill and all were bled to death on the fourth, fifth, or sixth day after the last inoculation. No area of fibrosis was seen in this group. Three of these animals produced serum which was hemolytic in a 1-5,000 dilution; 2 in a 1-10,000; 3 in a 1-15,000; and 2 in a 1-35,000 dilution.

It is hoped that some method of treating the serum will be evolved so that the reaction will be less severe and fewer animals will be lost. In spite of the high mortality the value of the method is apparent. In a series of 30 rabbits inoculated in 1925³ with sheep cells under varying conditions, only one responded with a serum hemolytic in a dilution above 1-10,000. Since we have been pursuing these experiments, workers in the State Bacteriological Laboratory have used the method with success though with a similar loss of animals.

CONCLUSION

The intracutaneous inoculation of rabbits with sheep serum and the subsequent intravenous injection of sheep cells was followed by the production of hemolysin of unusual power.

A SIMPLE LIGHT FILTER FOR MICROBLOOD SUGAR DETERMINATIONS*

J. W. MULL, PH.D., CLEVELAND, OHIO

IN A note on his microblood sugar method† Folin states that for satisfactory results one should use a light filter that will give a uniform field when a solution of 0.2 per cent potassium ferri cyanide set at 20 is matched against a cup of distilled water. A filter that will do this satisfactorily can easily be prepared by painting a rim of paraffin 2 to 3 mm. thick around the edges of a small section of an ordinary microscope slide. The cup so made is filled with a saturated solution of picric acid, the liquid covered with a cover slip, and the whole set on the eyepiece of the colorimeter, where it does not interfere with whatever source of light is being used.

A SIMPLE ROTARY INOCULATING TABLE*

ROBB SPALDING SPRAY, PH.D., MORGANTOWN, W. VA.

MECHANICAL devices have been frequently proposed and designed to facilitate dispersion of bacteria on agar plates for the purpose of surface colony isolation. These have been, for the most part, makeshifts, or are of complicated and expensive construction, involving the use of motor or other mechanical drives.

The design here proposed has the advantage of simplicity and cheapness of construction, and can be made in any university or commercial machine shop. It consists of only three parts: namely, a cast iron turntable, base plate, and a steel ball bearing. The table runs on a steel shaft turned to an oil tight

fit in the base, and is supported on a steel ball bearing. With a touch of the finger the table spins rapidly or slowly for a minute or more, according to the impetus given.

The table is provided with four holes into which small sticks may be inserted to protrude about $\frac{1}{16}$ inch to center the dish and prevent its slipping off center if turned at high speed. Or a disk of felt may be cemented onto the table which serves the same purpose.

In use the solidified agar plates are centered on the table. A loop of culture, from broth or agar, is placed in the center. The spreader, a triangular

*From the Department of Bacteriology, Medical School, The West Virginia University.

loop or glass rod bent to a right angle, is flamed and held in the right hand. The lid is lifted with the left hand just to allow the entrance of the spreader, and the table is spun counterclockwise with the right thumb. Spiral lines or confluent inoculation may be made according to experience. With some practice excellent colony distribution is effected. The procedure is more rapid, and the results much more uniform, than are obtained by the customary stroke method.

A METABOLISM CAGE FOR RATS*

KURT W. FRANKE, PH.D., AND W. ROYDEN FRANKE, BROOKINGS, S. D.

THE desire for a more economical cage, both from the standpoint of the cost and space required, resulted in the design of the cage unit shown in Fig. 1. This unit consists of 50 cages (25 to a side) and occupies a floor space 24 by 44 inches.

Fig. 1.

The cage proper (Fig. 2) is made in three pieces, the two sides are of galvanized iron, and the bottom and ends are of one piece of screen. The screen used is a $2\frac{1}{2}$ by $2\frac{1}{2}$ mesh, No. 063 wire, galvanized after weaving. The 24 inch width screen is cut into 8 inch pieces, and $\frac{1}{2}$ inch is turned over on a forming block after notches have been cut where the ends turn up. The side pieces are made of 24-gauge Armco galvanized iron and bent on a break as shown in the cross-section. These are then slipped onto the wire, the laps

*Communication No. 1 from the Department of Experiment Station Chemistry, South Dakota Experiment Station, Brookings.

Received for publication, May 18, 1933.

clined, and the corners soldered. It is best to clinch sides and solder when the cage is on a form so they will be interchangeable and slide freely into the hangers.

An opening is made in the screen by spreading the wire for inserting drinking tube, the bottle being held by a wire ring. If desired an opening

Fig. 2.

Fig. 3.

may be cut for the Joy food cup, which can be soldered on. If the wire edge does not make an even finish, strips of sheet metal can be bent on a break and soldered on as in Fig. 1.

Fig. 3 gives the dimensions and details for the construction of the stand which is made in two sections. When bolted together a sheet of galvanized iron is placed between, forming a solid back.

The $1\frac{1}{4}$ by $1\frac{1}{4}$ by $\frac{3}{16}$ inch angle and $1\frac{1}{4}$ by $\frac{3}{16}$ inch bar form the vertical supports and are welded last. Fig. 3 *A* and *B* give the detailed dimensions for the middle sections, the top (*C'*) varying from this by the substitution of an angle iron in front for the bar. The bottom section (*C'*) differs from the top by having this angle iron turned down, not requiring the angle and tees for hangers.

It was found advantageous to make a form in which to place the ends and sides for welding. The $\frac{1}{2}$ by 1 by $\frac{1}{8}$ inch angle for the hanger was then cut and spot welded. In order that the spacing be equal, templates of heavy sheet iron $8\frac{1}{8}$ inches wide were laid, and the tees for hangers were welded in place. As only a 1 by 1 by $\frac{1}{8}$ inch tee iron could be obtained, the unequal leg was cut by a torch to $\frac{1}{2}$ inch and ground smooth on an emery wheel.

The sections were then spaced $8\frac{3}{4}$ inches apart (this can be varied depending on the height of tray used to catch feces and urine), and the supporting angles and bars welded in place. As will be noted in Fig. 1, a 1 inch pipe and coupling were welded in the angle iron legs, so that the casters with 1 inch pipe thread sockets could be screwed into the couplings.

Pieces of galvanized iron were cut and laid over the top and middle sections to form the tops of the cages. On top of these, galvanized iron trays were slipped which, when filled with sawdust, catch the feces and absorb the urine.

When the iron angle framework is painted with aluminum paint, the unit has a neat and sanitary appearance.

List of material required for a unit:

- 24 ft. $1\frac{1}{4} \times 1\frac{1}{4} \times \frac{3}{16}$ inch angle
- 76 ft. $1 \times 1 \times \frac{3}{16}$ inch angle
- 15 ft. $\frac{1}{2} \times \frac{1}{2} \times \frac{1}{8}$ inch angle
- 30 ft. $1 \times 1 \times \frac{1}{8}$ inch tee
- 17 ft. $1\frac{1}{4} \times \frac{3}{16}$ inch bar
- 30 ft. $1 \times \frac{3}{16}$ inch bar
- 200 sq. ft. 24 gauge galvanized Armeo iron (cages and trays)
- 50 sq. ft. 26 gauge galvanized iron (back and tops of cages)
- 75 sq. ft. $2\frac{1}{2} \times 2\frac{1}{2}$ galvanized screen
- 6 pounds solder
- 6 ft. 1 inch iron pipe
- 4 1 inch couplings
- 1 set casters, 5 \times 1 inch Rubberex wheels, 1 inch pipe thread socket.

SUMMARY

A cage unit occupying minimum of space, very easy to clean, and very mobile (can be moved to balance for the weighing of rats and food, or from room to room).

A SIMPLE DEVICE TO BE USED IN CONNECTION WITH MICRO-KJELDAHL DIGESTION PROCESS*

HENRY PETERSILIE, B.S., NEW YORK, N. Y.

IT HAS been our experience that in the determination of the nonprotein nitrogen on the Folin-Wu blood filtrate by the micro-Kjeldahl method, the use of beads to prevent bumping of the liquid during the digestion has been unsatisfactory. The flame needs careful regulation and very often, in spite of

gentle heating and constant attention, the determination may be lost through bumping out of the tube.

The tube herein described has been used in the determination of the boiling points of small quantities of pure liquid. We have adapted it to the non-protein nitrogen determination. Its advantages are:

*From the Pathological Department, Bronx Hospital.

Received for publication, May 1, 1933.

I am indebted to Dr. Joseph Felsen, Director, for encouragement in publication of above method.

1. It prevents bumping.
2. It permits a uniform rate of boiling and makes possible the "eight minute" period for the digestion.
3. It needs no watching and many determinations may be run at the same time without fear of losing any of the mixtures.
4. It may be used repeatedly.

The device consists of a piece of Pyrex glass tubing sealed at one end, 7 mm. in length and of 3 mm. inner diameter, (*A*), attached to a Pyrex glass rod, 20 cm. in length, (*B*), and of the same diameter as (*A*). The sealed end of (*A*) is fused onto the glass rod, leaving the lower end open. The device is inserted into the bottom of the micro-Kjeldahl tube containing the blood filtrate and the "acid digestion mixture." Gentle heat is applied and after boiling has started, the digestion needs no attention until the final charring and color changes. The tube is not removed until after nesslerization; for some of the liquid goes into the open end of (*A*) and its removal at this point would introduce a source of error.

The evaporation of a liquid depends on heat transfer to the liquid through a solid containing wall. The rate of evaporation depends, among other factors, on the thickness of the film between the inner surface of the container and the liquid. This film offers the greatest resistance to heat transfer.* Superheating of the film causes sudden vaporization at the bottom of the liquid and "bumping." Smoothness and cleanliness of the solid surface are important factors in the coefficient of heat transfer.

Tube "*A*," in order to be effective, must rest in the bottom of the digestion tube. This contact compresses the film at that point and causes flashing at a lower temperature. "*A*" receives the vapor and issues it in a steady stream of small bubbles.

Thus, this device is explained by vaporization at a lower temperature, superheating of only a small portion of the liquid film, and the convection of heat by the bubbles.

DEPARTMENT OF REVIEWS AND ABSTRACTS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

PREGNANCY, Hormone Diagnosis of Viability of, Spielman, F., Goldberger, M. A., and Frank, R. T. J. A. M. A. 101: 266, 1933.

Thirty-three pregnancy cases in which missed abortion was suspected or expected were studied from the hormonal aspect in order to determine the relationship between the female sex hormone of the blood and the prepituitary hormone of the urine on the one hand, and fetal life or death on the other.

The Frank-Goldberger method was used in the blood studies, and either the Aschheim-Zondek or the Friedman test in the urine studies.

A negative female sex hormone reaction was obtained when the fetus was dead (twenty-three cases) and a positive reaction when the fetus was alive (eight cases). The results here were 100 per cent correct.

A negative pregnancy reaction was obtained when the fetus was dead in eleven cases, and ten cases gave positive reactions in spite of dead fetuses (approximately 50 per cent correct).

The female sex hormone blood determination has proved itself in our small series an absolute indicator of whether a fetus is alive or dead. The urine pregnancy test is of value only when the reaction is negative.

The presence or absence of the hormones depends on the degree of involution of the placenta and its attachment to the uterine wall.

PNEUMONIA, Significance of the Newly Classified Types of Pneumococci in Disease, Sutliff, W. D., and Finland, M. J. A. M. A. 101: 1289, 1933.

This general survey of the incidence of twenty serologically specific strains of pneumococci and of hemolytic streptococci, staphylococci and Friedlander bacilli in the pneumonia cases in a general hospital in an interepidemic period shows that each one of these organisms may cause the disease. The rare type-specific pneumococci numbered from IV to XX are consistently present in the sputum and lesions in certain cases of lobar pneumonia and bronchopneumonia. The presence of such pneumococcus strains in the sputum of patients with pneumonia is a reliable indication of their presence in the lung.

Exact etiologic diagnoses of pneumococcic pneumonia were made by the use of seventeen of the new typing serums, in a group of cases in which this has heretofore been impossible, amounting to 30 per cent of the total number of lobar pneumonia cases, and in 65.1 per cent of the relatively little understood and important group of bronchopneumonia and secondary pneumonia.

The order of frequency of the six most frequent pneumococcus types in pneumococcic lobar pneumonia is as follows: I, II, III, VIII, V and VII, making together 84.1 per cent of the cases, and the order of frequency of the ten most frequent types in pneumococcic bronchopneumonia is: III, VIII, XVIII, X, V, VII, XX, II, XI and XIV, making altogether 81.1 per cent of the cases. The six types most frequent in lobar pneumonia are also those most frequent in the whole series and have been given more attention than the others.

Certain individual characteristics of the pneumonias caused by the new pneumococcus types from IV to XX are brought out and compared with the better known Types I, II and III. The three most frequent of the newer types are V, VII and VIII. Type V makes up 5 per cent of the total of pneumococcic pneumonias or empyemas and causes either pneumonia or empyema in 96 per cent of the cases in which it is found and leads to purulent complications in 28 per cent of the pneumonia cases. Type V is associated with lobar pneumonia

rather than bronchopneumonia in only 81 per cent of the cases, in which respect it resembles most of the newer types. Its age distribution is quite irregular and without the usual preponderance in middle life. Type VII is associated with pneumonia or empyema in only 80 per cent of the cases but leads to purulent complications in 11 per cent, a rather high proportion of these pneumonia cases. Type VIII is associated with pneumonia or empyema in 90 per cent of the cases in which it is isolated and has a low mortality in lobar pneumonia, 23.8 per cent, but, owing to an average bronchopneumonia mortality of 67 per cent, has a total mortality near the average.

The experience afforded by the bacteriologic classification of this series of pneumonia cases has indicated that the pneumonias due to different serologic strains of pneumococci and due to other organisms may be regarded as separate entities. By identifying such organisms in every case, the clinician may make accurate etiologic diagnoses and prognoses, the epidemiologist may unravel the factors affecting the organism and the patient leading to the development of atypical and secondary pneumonia, and the physician may apply the large amount of information about pneumococcus type specificity to the cure of and protection from pneumococcal infections.

PNEUMONIA, Epidemiology of, Prevalence of Specific Strains in Immediate Family Contacts, Smillie, W. G. J. A. M. A. 101: 1281, 1933.

In a study of over a thousand persons, Type I and Type II pneumococci were found to be much more prevalent in the nasopharynx in immediate family contacts of cases of lobar pneumonia due to the homologous type than in the population at large.

The higher types of pneumococci—Types III to XIX, inclusive, were just as prevalent in the throat in the general population as in the family contacts of cases of pneumonia due to these specific types. The types most frequently encountered were III, VI and XVIII.

The whole group of pneumococci was less prevalent in the late summer months than in the winter and early spring. No one type of pneumococcus showed any deviation from the general rule in seasonal distribution.

Poor economic conditions, with resultant overcrowding, did not, per se, increase the prevalence of any one specific type of pneumococci in contacts of pneumonia due to the homologous type.

The studies suggest that epidemics of family colds have some relationship to the prevalence of the homologous types of pneumococci in contacts of lobar pneumonia due to Type I and Type II.

LEUKOCYTES: An Unusual Hematologic Reaction to Neoarsphenamine, Rich, M. L. J. A. M. A. 101: 1223, 1933.

In a case of acute thrombocytopenic purpura following an injection of neoarsphenamine, a smear taken three hours after the injection showed, in addition to the thrombocytopenia, the presence of numerous degenerated neutrophilic cells. There was also evidence of intense marrow stimulation. These conditions quickly disappeared. It is concluded that neoarsphenamine at times has not only a toxic depressant action on the bone marrow but also a destructive action on some of the circulating elements of the blood, and that the neutrophilic cells as well as the platelets are susceptible to its action.

TUBERCLE BACILLI, Routine Culture of the Urine for, Seidman, L. R. J. Urol. 30: 2: 195, 1933.

This is a study of cultural methods in comparison with guinea-pig inoculation. The routine method used was as follows:

Ten cubic centimeters of the suspected urine, collected by catheter, are transferred by pipette, under sterile precautions, to each of 2 centrifuge tubes, and centrifugized at high speed for thirty-five to forty-five minutes. The clear supernatant fluid is then decanted, the sediment smeared on a clean new slide, and after fixation with heat, stained by Ziehl-

Neelsen. If no acid-fast bacilli are found after careful search a guinea pig is inoculated subcutaneously in the groin, with an emulsion of the remaining sediment in 1.0 c.c. of normal saline. The guinea pigs are examined weekly for the development of a gross lesion at the site of inoculation, and enlarged inguinal nodes. When these become definite, the animal is killed, an autopsy performed, and the lesions examined for acid-fast bacilli. If gross lesions do not develop, guinea pigs are killed, and autopsies done two months after inoculation.

All specimens, whether positive or negative, were cultured.

From a study of 89 specimens from 45 cases the following conclusions were drawn:

Eighty-nine specimens, from 45 cases, 81 of them bladder or kidney urine, were cultured. Tubercle bacilli were isolated from 60, or 67.4 per cent, of the specimens, and from 39, or 86.6 per cent of the cases. In 14 of the positive cultures, no acid-fast bacilli had been seen in the direct smear of the concentrated sediment. From 14 specimens, in which acid-fast bacilli had been seen in the direct smear, no growth was obtained. In 15 specimens, in which both culture and direct smear were negative, the inoculated guinea pigs developed tuberculosis.

Growth of tubercle bacilli was obtained on Corper's crystal violet potato cylinder from 54.0 per cent of the positive sediments, on Petroff's coagulated egg medium (without gentian violet), from 69.1 per cent, and on Sweany's milk meat infusion, egg and cream medium from 71.6 per cent. Corper's potato is a more satisfactory medium than these results indicate.

Five per cent oxalic acid, and 3 per cent sodium hydroxide proved better as digestants than 6 per cent sulphuric acid, both in the percentage of isolations, and in the average time required for the appearance of growth. All 3 reagents were equally efficient in destroying secondary contaminants.

The shortest interval for the primary isolation of tubercle bacilli by culture was sixteen days. Growth was obtained within three weeks in 18.3 per cent of the positive specimens, on 7.0 per cent of the inoculated culture tubes.

For the reasons discussed, guinea pig inoculation still appears to be superior to cultures for the diagnosis of tuberculosis in suspected cases.

No avian strains of tubercle bacilli were recovered. Strains from 18 cases were of the human type, and the remainder showed the growth characters of the mammalian organisms.

LUNG, Primary Carcinoma of, Hruby, A. J., and Sweany, H. C., Arch. Int. Med. 52: 497, 1933.

An epidemiologic and clinical study has been made of primary cancer of the lung, with reports of 13 cases, 12 of which were unquestionably primary in the lungs and bronchi and 1 primary in the ovary. There has been an approximately tenfold increase in the number of cases of cancer of the lung coming to autopsy within the last forty years, and a twofold increase in the last ten years. There is no valid evidence, however, to prove an increase in the general incidence of the disease except where there is contact with radioactive dust (Schneeberg and Joachimstal miners). The increase that has occurred may be partly accounted for on the basis of (1) the increased life expectancy from forty-three to fifty-eight years in approximately the last half century; (2) a better knowledge of the causes of other pulmonary diseases (e.g., the knowledge resulting from the discovery of the tubercle bacillus); (3) better diagnostic equipment (x-ray apparatus, bronchoscope and similar equipment); (4) increased zeal on the part of the medical profession and laity (better hospitalization, better transportation and other factors); (5) a changed attitude on the part of the pathologists in recognizing as primary carcinomas tumors that were once called metastases and sarcomas. It is not justifiable therefore to claim an increase in cancer of the lung until all the unknown factors are studied (such as the relative number of cancers of the lung that occur in rural districts).

For a diagnosis, reliance should be placed on a gradually appearing cough (commonly in men past middle life), followed by a variable but constant pain, and expectoration of sputum frequently streaked with blood, all of which may be accompanied with or followed by dyspnea.

Other less common signs are anorexia, fever, loss of weight, symptoms due to pressure (dysphagia and aphonia) and a variety of symptoms due to metastases. The physical signs reveal the presence of a gradually increasing bronchial tumor, with limitation of motion of the affected side, slight or no moisture at first, decreased breath sounds distal to the bronchial obstruction, hyperresonance above, dullness, and ultimately flatness over the tumor. The roentgenogram reveals a gradually progressing growth of tumor out from the hilus or along a bronchus, and the growth may be diffuse or circumscribed. The endoscopic view reveals a "woody" or fixed bronchus, and study of a bronchoscopic section generally clinches the diagnosis.

The laboratory examination should first reveal a scant or mucoid sputum, sometimes streaked with blood or tinted with hemoglobin, free from tubercle bacilli. Later, tumor cells should be found in the sputum or pleural fluid. Such early findings offer the only opportunity for permanent therapeutic aid.

A pertinent observation has been recorded pertaining to distant metastases from cancer of the lung. They seem to depend on the rapidity and extent of the growth of the primary tumor into a pulmonary vein.

UREA CLEARANCE, Test in Pregnancy, Cantarow, A., and Ricchiuti, G. Arch. Int. Med.
52: 637, 1933.

Determinations of urea clearance were made in thirty-nine cases of normal pregnancy and in seven cases of chronic glomerulonephritis and one of myocardial failure complicating pregnancy.

In the normal group, the urea clearance values ranged from 28 to 184 per cent of the average normal as established by Van Slyke and his associates.

The urea clearance, which was normal in the first few months of gestation, diminished as pregnancy progressed, being rather consistently low a few days before the onset of labor. High values were obtained during the early days of the puerperal period.

It is suggested that these findings may be dependent on changes in total metabolism and protein metabolism, fetal development and alterations in the rate and volume of blood flow through the kidneys.

It is further suggested that the laws governing the elimination of urea in the nonpregnant state, which form the basis of the mathematical calculation of the blood urea clearance, may not apply to the pregnant state because of the physiologic changes mentioned.

Subnormal clearance values obtained during the last two months of gestation must be interpreted with extreme caution, particularly in the absence of clinical or laboratory evidence of renal dysfunction.

CARCINOMA, Breast, The Bases for Histologic Grading of, Haagensen, C. D. Am. J. Cancer 19: 285, 1933.

In a series of 164 cases of carcinoma of the breast, which was exceptionally advantageous for the study of the relationship of histologic structure to prognosis because of the remarkably complete follow-up data and because of the superior quality and the large number of the histologic sections, a careful analysis has been made of the prognostic significance of fifteen different histologic characteristics. Six of these characteristics have been found to have a probable relationship to the end-result of the treatment. These significant characteristics are, in fact, similar to those which Hanseemann originally proposed for the determination of grade of anaplasia. The factors of fibrosis and lymphocytic infiltration, more recently stressed in tumor grading, have been found to be without prognostic import.

On the basis of these six significant histologic characteristics, it would appear that breast carcinomas can be classified into three grades of malignancy, in which the increasing grade of anaplasia parallels an increasing grade of malignancy as evidenced by the tendency of the tumor to metastasize and kill the patient at an early date.

It should be remembered that prognosis based on this type of histological evidence cannot claim a mathematical accuracy. It should be regarded only as an approximation, and a

rough one at that. The phenomenon of malignancy which we are attempting to measure is a biological one, and does not lend itself to exact measurement in mathematical terms. Moreover, the extremes, that is the Grades I and III, should be given more weight than Grade II, the less definite middle class into which a great proportion of breast carcinomas fall.

This knowledge gained from histologic grading should not be regarded as in any sense competing with the clinical data bearing on prognosis, to which it is, of course, subordinate in importance. Histologic grading should rather be considered as a new and additional form of information, as a modest but yet valuable increment to the knowledge of the disease.

The histological characters above referred to as having prognostic significance are:

1. Papillary character: origin in a cyst formed in a duct.
2. Comedo character: origin mainly within ducts, often with central necrosis.
3. Adenoid arrangement of cells: A, marked; B, slight; C, absent.
4. Variation in size and shape of nuclei: A, slight; B, moderate; C, marked.
5. Number of mitoses: A, few; B, moderate number; C, numerous.
6. Gelatinous degeneration.

DIABETES MELLITUS, Characteristics and Trends of Diabetes Mortality Throughout the World, Joslin, E. P., Dublin, L. I., and Marks, H. H. Am. J. M. Sc. 186: 754, 1933.

Analysis of available mortality data on diabetes in this country and abroad during the present century brings out these main features.

Diabetes as a cause of death has been rapidly growing in importance during the present century and is now one of the leading causes of death in this country.

The mortality from diabetes in this country is higher than in other parts of the world.

Diabetes death rates are increasing all over the world.

Most of the deaths from diabetes occur after middle life. Among children and young adults, the mortality from the disease is low. It begins to loom large about age forty and the rise in the death rates by age thereafter is rapid.

Up to age thirty-five present death rates of males and females are little different, but after that age the rates of women are the higher. This excess of the female death rate increases with advancing age up to sixty-five, when it is about twice that of males.

The high diabetes mortality in this country, as compared to other countries is not limited to one sex, but is found among both men and women. It is also found to exist at almost every age past thirty-five.

The diabetes mortality among negroes in this country has been increasing at a more rapid rate than among whites, and is now not much lower than that of whites.

SALMONELLA SUIPESTIFER, Infection in a Child, Haynes, E., and Meeks, L. T. Am. J. Dis. Child. 46: 1054, 1933.

It is apparent from a review of the cases described in the literature and the one reported here that infection with *S. suipestifer* does not produce any one characteristic clinical picture. Most commonly the gastrointestinal tract has been attacked. The symptoms and signs when this occurs sometimes resemble those of so-called food poisoning, such as is frequently caused by *S. enteritidis*; sometimes they are like typhoid or paratyphoid fever, and, in one case reported, the disease resembled bacillary dysentery. Next in frequency is involvement of the respiratory tract, where the infection may manifest itself as a bronchitis or as bronchopneumonia or lobar pneumonia. Symptoms referable to both the gastrointestinal and the respiratory tracts may occur together, as happened in the case reported. In addition to these more common manifestations, single examples have been reported of suppurative arthritis, sudden deafness, inflammation of the soft tissues around the jaw, puerperal infection with pleural effusion, peripheral neuritis and infarcts of the kidneys. Since infection with *S. suipestifer* can apparently cause a considerable variety of clinical manifestations, it seems advisable that in the investigation of any case of obscure fever, especially those associated with gastrointestinal symptoms, bacteriologic studies should be carried out with particular reference to this organism.

CALCIUM AND PHOSPHORUS, Blood, Concentration of in Serum of Normal Children,
Schoenthal, L., and Lurie, D. K. *Am. J. Dis. Child.* 46: 1038, 1933.

A study of the calcium and phosphorus of the blood serums of 250 normal children from five to sixteen years of age was made. There was no change in the level of calcium in relation to age. Phosphorus showed a significant decline, beginning with the fifteenth year of life. This occurred to a more marked degree in the girls than in the boys.

No clear-cut relation between the levels of calcium and phosphorus and growth was found.

The spontaneous variation of calcium and phosphorus was of the same magnitude as that seen after the ingestion of an ordinary breakfast.

Administration of viosterol in dosages of from 10 to 40 drops daily, or of 1 quart of milk, did not regularly increase the levels of calcium and phosphorus in these children.

PERITONEAL INJECTIONS, Changes in the Composition of Fluids Injected Into the Peritoneal Cavity, Schlechter, A. J., Cary, M. K., Carpentieri, A. L., Darrow, D. C. *Am. J. Dis. Child.* 46: 1015, 1933.

The changes occurring in electrolytes of various solutions when injected into the peritoneal cavity of dogs and guinea pigs were studied. The following solutions were used: (1) 0.9 per cent sodium chloride; (2) a mixture of sodium chloride, sodium carbonate and potassium chloride resembling interstitial fluid; (3) Hartmann's solution of sodium chloride, potassium chloride, calcium chloride and sodium lactate and (4) 5 per cent dextrose solution.

In each case the solutions injected into the peritoneal cavity underwent alterations in electrolyte concentration which indicate that they tend to approach the composition of interstitial fluid.

Electrolyte solutions were absorbed at an approximately constant rate, but the dextrose solution increased in volume before being absorbed.

It is pointed out that isotonic dextrose solutions undergo such great alterations in concentration and volume that subcutaneous or intraperitoneal injection probably is injurious to delicate tissues.

B. TUBERCULOSIS, Inhibitory Effect of Normal Blood on Growth of at Incubator Temperature, Corper, H. J., and Vidal, C. B. *Am. Rev. Tuberc.* 28: 878, 1933.

The growth of human and bovine tubercle bacilli on good media is inhibited by normal blood from dogs or rabbits. This inhibition is more evident with small numbers of bacilli than it is with large numbers and it is more evident on inspissated egg yolk than it is on potato.

The effect is due to the development of toxic autolytic products from normal blood, and is absent when the blood has been treated with one or two volumes of 6 per cent sulphuric acid for one-half to one hour at 37° C., which destroys the autolytic enzymes, followed by neutralization with isotonic sodium bicarbonate solution (or other nontoxic alkalies). Regardless of the treatment, however, accurate determination of the number of tubercle bacilli placed in blood is not possible by counting the colonies which this blood will yield on good media suited to growing small numbers of human and bovine tubercle bacilli from fine suspensions.

Sulphydryl and Cellular Multiplication

IN A SEARCH for further knowledge concerning the causation of cancer a group of investigators in Philadelphia have made a most interesting and important observation concerning the manner in which living cells are stimulated to reproduce themselves. The bearing of this observation on cancer is obvious if we realize that cancer is a disease in which the living cells of the body take on the capability of multiplying unrestrainedly and at the expense of surrounding tissues and organs. However, the immediate practical result of the research turns out to be in an entirely different field of medicine.

The investigation, conducted in the Research Institute of the Lankenau Hospital, was first directed to purely scientific attempts to study the division of living cells. The tissue that presented itself as being particularly appropriate for this was the root tip of the common onion. After a long period of investigation it became apparent that if some sulphur compound were made

readily available in the fluid in which the roots were growing the cells thereof would multiply more rapidly. Conversely in the absence of a sulphur compound reproduction was slowed down. It was found that the best sulphur compound for this purpose was the combination of sulphur and hydrogen, termed sulphydryl. Doctors Hammett and Reimann suspected that this might actually be the compound which stimulates cells to divide and multiply, since it is present in all living tissues.

While sulphydryl can in no way be looked upon as the cause of cancer, and as yet, no way seems clear to utilize this knowledge (such as by the restriction of sulphydryl in the food, or the administration of some substance that would neutralize its effect), for the practical application of this knowledge in the prevention or cure of cancer, the knowledge does represent one forward step in our halting progress of the study of this malady.

It is most interesting that glutathione, a substance containing a sulphydryl group in its chemical make-up, is present in all animal tissues. Glutathione contains the amino acids cysteine, glutamic acid, and glycine. The sulphydryl group occurs in cysteine. Cysteine is most abundant in the liver, an organ of unusual cellular activity and in epithelial structures, particularly hair. It is highly concentrated in wool and especially concentrated in human hair. It probably accounts in part at least for the rapid growth of human hair.

But it is equally interesting that it has been demonstrated that glutathione, with its constituent cysteine, is present in cancers in quantities almost as large as those found in the liver.

Hammett and Reimann have shown not only that the cells of the onion plant are stimulated by sulphydryl to reproduce, but likewise the normal tissue cells of man and the living cells of bacteria. Recently two independent workers at the National Institute of Health, Doctors Voegtlin and Chalkley, have demonstrated that glutathione serves equally well as a stimulant for reproduction of the ameba. The evidence appears to be accumulating that sulphydryl or some compound containing sulphydryl does actually stimulate multiplication of any type of living cell no matter what its nature.

The immediate practical application of this knowledge has been in the treatment of cutaneous ulcers which have either failed to heal or are healing very slowly under other methods of treatment.

Reimann applied dressings soaked with sulphydryl compounded with glucose (thioglucose) in the treatment of indolent ulcers which had resisted other methods. He found that while the edges of the ulcer tended to heal due to proliferation of the adjacent skin, bacteria infecting the wound also multiplied vigorously, apparently due to the sugar content of the thioglucose. He then changed his combination of sulphydryl, hitching it up chemically with an antiseptic, cresol, in the form of parathiocresol. He then achieved excellent healing. Later it was observed that glutathione itself would do as well.

Brunsting and Simonsen of the Mayo Clinic in an effort to find a substitute for the expensive glutathione discovered that cysteine itself was equally efficacious. They extracted cystine from human hair by hydrolysis and converted it into cysteine hydrochloride. This was used on the wet dressings ap-

plied to wounds. They found cysteine not only as efficient as thio cresol but less irritating to the adjacent skin and free from unpleasant penetrating odor of burnt rubber that is a feature of the latter.

The cysteine treatment of bed sores, ulcers following burns, slowly healing carbuncles, ulcers from injuries, ulcers from x-ray burns, serofulous sinuses, and the like is materially improved. Skin grafts show a decidedly better "take." In a series of 200 cases treated with cysteine, a decided stimulation to healing due to the cysteine was observed in 50 per cent, while in an additional 25 per cent, the beneficial effect was reported as promising. The cysteine treatment of ulcers is not a substitute but an adjunct to the other well-established procedures.

One can readily understand that sulphydryl compounds should not be used in the treatment of cancerous ulcers.

It is interesting in connection with the practical application of our knowledge of the action of the sulphydryl group in the treatment of the skin, to realize that the skin and its appendages are naturally rich in sulphur and also that dermatologists have long used sulphur, thus unconsciously attempting to stimulate the tissues of the skin to greater activity.

CLINICAL AND EXPERIMENTAL

EFFECTS OF LOW TEMPERATURE RETARDATION IN THE CULTURE OF STERILE MAGGOTS FOR SURGICAL USE*

WM. ROBINSON, PH.D., AND S. W. SIMMONS, A.M., WASHINGTON, D. C.

A LARGE number of laboratories, chiefly connected with hospitals, are now engaged in the culture of blowfly maggots for use in the Baer method¹ of treatment of infected wounds. In the cultural process it is necessary to hold back the rapid development of certain immature stages,² and it appears to be customary to do this by means of low temperature. Owing to the widespread use of this method of retardation and to observations made in the Bureau of Entomology which indicated that this procedure has certain limitations, an investigation has been made of the general effects of such retardation upon the normal functions and mortality of all stages held back in this way. A mechanical refrigerator running at from 40° to 43° F. was used. This range was found to be low enough to retard development, and is probably accessible to most laboratories. *Lucilia sericata*, the species commonly reared for the maggot treatment, was used in these experiments.

THE EGG

It is the usual practice to remove eggs from the fly cages in the afternoon and place them at once in cold storage for disinfection the next morning. It frequently happens also that a surplus of eggs is laid and they are stored until

*From the Division of Insects Affecting Man and Animals, United States Bureau of Entomology.

Received for publication, July 3, 1933.

needed. The length of time eggs may be retarded without injury, under various methods of storage, was tested in this series.

Source of Eggs.—All eggs used were produced under uniform conditions of temperature, moisture and food. Also, since the age of the female affects the viability of her eggs, the females were used only during the first three weeks of oviposition. Eggs were taken within two hours of deposition.

Methods of Storing.—(1) Eggs were left upon the meat and placed in covered Petri dishes. (2) Eggs were removed from the meat and placed in vials of water. (3) Eggs were removed from the meat and placed upon moistened cloth over a wet cotton pad in a covered Petri dish.

Since the eggs are usually laid in masses and are difficult to count, the weight method³ of determining number was used. Eggs were removed from storage at intervals up to 3 days and given a viability test.³

Effect of Age of Egg upon Survival.—It soon became evident that the degree of development of the embryo at the time of storage of the egg was important (Table I). When eggs freshly laid and up to two hours of age were

placed in storage for twenty hours, only 32.5 per cent of the normal hatch occurred, whereas eggs two to four hours old when stored produced 97 per cent of the normal hatch. Therefore, only eggs which had been laid two to four hours were used. They were obtained by removing the meat from the fly cages after two hours and keeping it in the warm incubator for the additional two hours before storage.

Results.—Cold storage has a destructive effect upon the egg, as shown in Table II. Even the twenty-hour exposure, which is only slightly greater

TABLE II
LENGTH OF TIME EGGS CAN SURVIVE COLD STORAGE

TIME IN STORAGE (HOURS)	NUMBER OF TESTS MADE	NUMBER OF EGGS USED	SURVIVAL (PER CENT)
20	9	2,603	67.4
28	9	2,742	66.5
36	9	2,588	48.3
45	9	2,366	40.1
58	9	2,423	18.2
72	9	1,489	1.8

(Normal hatch, 77 per cent)

than the customary overnight storage, reduced the normal hatch by 12.5 per cent. The mortality was increased rapidly with length of exposure, and after three days' storage almost the entire number was destroyed. No difference in effect was observed among the three methods of storage. Mortality was greatly increased when eggs were removed directly from the fly cages to the refrigerator.

THE SURGICAL MAGGOT

Owing to the irregularity in the demand for sterile maggots a surplus frequently occurs. The expense of production would be reduced if any surplus could be stored safely until needed. Experiments were therefore conducted to determine the mortality under cold storage. The name "surgical maggots" is applied here to sterile maggots ready for use in wounds and about 4 to 6 mm. in size.

The maggots used in these tests were produced under the same sterile conditions as for use in wounds,² but in smaller lots of about 200 each. They were stored with some food in glass rearing bottles³ from one to six days.

Survival Tests.—As a check on their tolerance of cold storage, it was required that the maggots should be able not only to move when restored to the warmth of the laboratory but to resume feeding and growth. It is obvious that maggots which cannot feed are of no use clinically. Accordingly all maggots living when removed were placed upon raw beef to test feeding capacity.

Results.—A high rate of mortality occurs in cold storage of surgical maggots (Table III). The last column shows that even when stored only one

TABLE III
LENGTH OF TIME SURGICAL MAGGOTS CAN SURVIVE COLD STORAGE

TIME IN STORAGE (DAYS)	NUMBER OF EXPERIMENTS MADE	NUMBER OF MAGGOTS USED	NUMBER WHICH SURVIVED STORAGE	NUMBER ABLE TO RESUME FEEDING	SURVIVAL (PER CENT)
1	7	3,006	2,655	1,104	37.9
2	6	2,764	1,650	922	33.3
3	6	2,823	1,112	604	22.2
4	5	2,183	781	397	18.2
5	4	985	391	119	12.2
6	2	448	55	7	1.5
(Normal survival, 81 per cent)					

day less than 40 per cent were able to resume feeding. The mortality, increasing rapidly, amounted to almost 100 per cent in six days. Maggots reared under the same conditions but not stored had a normal mortality of only 19 per cent. Death of surgical maggots under the usual method of cold storage is therefore very considerable.

The fact that cold storage is very injurious to surgical maggots is evident not only in the number of maggots which were killed outright while in storage, but also in the inability of about one-half of the survivors to feed and continue their development. These latter losses easily escape detection unless closely observed. Cold storage of surgical maggots should therefore be avoided.

A Method of Avoiding Cold Storage of Surgical Maggots.—The only time that storage of maggots is essential in the cultural technic as ordinarily practiced is during the sterility tests,² when the growth of the maggots is held back in the refrigerator for forty-eight hours. Such retardation of growth by low temperature, however, is no longer necessary as a food has been devised by one of us (S. W. S.) which prevents the maggots from growing too large during the sterility tests. This food permits only a slow rate of growth throughout the cultural period, but does not interfere with normal feeding of the maggots when implanted in the wound. It consists of 1 part of evaporated milk to 5 or 7 parts of water, to which is added 1.5 per cent plain agar. This mixture is cooked in a double boiler for about twenty-five minutes and approximately 15 c.c. is used in each food bottle.

PREPUA

This stage is a convenient one for storing, as the larvae have already migrated from their food and are easily collected and handled.

Method of Storing.—Prepupae were taken from the sand about thirty-six hours after migration and while they still resembled larvae. The containers used were the common oiled paper or fiber cans, half-pint size, which are readily obtainable. They are waterproof and have a fairly tight-fitting lid. About one inch of dry sand was placed in each container along with the specimens. If a much larger quantity of sand is used, it should previously be chilled to storage temperature, otherwise the prepupae tend to develop to the pupal stage before the sand is cooled. It is important to prevent such development, as pupae are much less tolerant of storage than prepupae, as will be shown in the next section.

Loss of Weight During Storage.—Preliminary tests had shown that when no special precautions were taken to provide air-tightness in the containers, a noticeable loss of weight of prepupae occurred in storage. During the present experiments an investigation was made of the cause of shrinkage and methods of prevention. Specimens were stored in the containers under three different degrees of air-tightness. (1) Container was sealed with adhesive tape around the edge of the lid. (2) Container was not sealed and the lid fitted in the ordinary manner. (3) Container was the same as No. 2 but had numerous pinholes in the lid.

Each time specimens were removed from storage for survival tests, an equal number (twenty-four) were taken out and desiccated to constant weight at 100° C. for determination of weight losses.

Survival Tests.—Removals from storage were made at the intervals shown in Table V. The mere ability of prepupae to revive and move in the warm air of the laboratory was not considered sufficient indication of survival. Development into adults and oviposition of viable eggs by the females were considered necessary parts of the test. Accordingly, each lot when removed from storage was placed in a rearing cage, and the necessary care was given up to oviposition. When eggs were laid a viability test³ was made in each case.

Results.—The percentage of water and solid losses under the three methods

of storage are given in Table IV. Loss of water began at the outset of storage and continued throughout the period. Specimens stored in the sealed containers lost the least in both water and solids.

As to survival from storage, Table V shows that in two to four weeks no considerable mortality occurred, as 15 per cent is the normal death rate without storage. Holding beyond four weeks, however, caused a rather high death rate, and after nine weeks the mortality was 60 to 70 per cent.

The lowest mortality always occurred in the sealed containers. There is therefore a correlation between death rate and loss of weight in storage. Apparently when the water content is decreased below 33 per cent the mortality becomes especially high.

TABLE IV
EFFECT OF METHOD OF STORAGE UPON LOSS OF WEIGHT OF PREPUPAE

TIME IN STORAGE (DAYS)	PERFORATED CAP		ORDINARY CAP		SEALED CAP	
	WATER (PER CENT LOSS)	SOLID (PER CENT LOSS)	WATER (PER CENT LOSS)	SOLID (PER CENT LOSS)	WATER (PER CENT LOSS)	SOLID (PER CENT LOSS)
7	10.4	0.2	12.1	0.2	4.2	0
14	14.7	0.3	15.6	0.3	9.8	0
21	19.9	0.4	17.6	0.3	15.3	0
35	24.8	0.5	23.9	0.4	22.1	0.3
49	32.3	0.7	34.0	0.8	31.0	0.7
62	38.2	0.9	38.5	1.0	36.6	0.8
76	44.4	1.9	44.4	1.9	41.1	1.1
91	46.4	2.3	48.3	2.2	42.1	1.5
105	48.3	2.3	50.0	2.3	43.4	1.8

Another unfavorable aspect of cold storage of prepupae, which is not readily apparent, is the reduced egg-laying capacity of surviving females. In 9 colonies of flies which had been stored from three to four weeks as prepupae, it was found that the length of life of the flies was only one-half that of the preceding generations which had not been stored, and that the number of eggs laid was reduced to one-third of the normal.

TABLE V
EFFECT OF COLD STORAGE UPON PREPUPAE

TIME IN STORAGE (DAYS)	PER CENT SURVIVAL		
	PERFORATED CAP	ORDINARY CAP	SEALED CAP
16	83.5	67.8	83.5
33	60.5	54.2	66.6
49	45.8	45.8	62.5
62	29.1	29.1	37.5
76	18.3	24.1	37.5
91	18.3	19.1	20.8
105	12.5	8.3	12.5
(Normal survival, 85 per cent)			

THE PUPA

Pupae, being especially easy to handle and store, and requiring no food or attention, constitute a very convenient stage for storing. Reserve stock is frequently held in this stage.

Method of Storage.—The pupae were used when about thirty-six hours old. They were placed in the same three types of containers as used for prepupae. The same standard tests for survival were also made.

Results.—It soon became evident, however, that pupae could not be satisfactorily held over, as they were unable to endure even a moderate period of storage. After the second week the emergence fell to almost one-third of the normal, and most of the eggs which were laid failed to hatch (Table VI).

TABLE VI
SURVIVAL WHEN STORED AS PUPAE

TIME IN STORAGE (DAYS)	SURVIVAL (PER CENT)
7	66.6
15	37.5
22	15.2
29	11.1
36	8.2
43	2.7
(Normal survival, 86 per cent)	

After three weeks of storage the females which emerged died at an early age and laid no eggs. The type of container appeared to have no effect upon the results obtained with pupae.

SUMMARY AND CONCLUSIONS

In the production of surgical maggots it is customary to retard the rapid development of the immature stages by holding them in reserve under cold storage. An investigation has been made of the tolerance of the egg, surgical maggot, prepupa, and pupa to various periods of retardation.

Eggs may be kept in a closed container in a refrigerator at 40° to 43° F. overnight and up to twenty-eight hours with a mortality only slightly greater than normal, but continued storage is very unfavorable, and in three days results in almost complete destruction.

The age of the egg when stored affects the degree of injury. The lowest mortality occurred when eggs were allowed to remain in the warm incubator an additional two or three hours after removal from the fly cages before being stored.

Surgical maggots cannot satisfactorily be kept in cold storage. After twenty-four hours' retardation only 40 per cent were able to resume feeding, and in six days almost 100 per cent destruction occurred. A retarding food is described which eliminates the need of cold storage during the sterility tests.

Prepupae are best adapted to cold storage, but even in this stage the possibilities are considerably limited. They lose weight and become shrunken during cold storage. This is mostly water loss. Least unfavorable results were obtained with a relatively air-tight container. In thirty-three days the mortality was from 33 to 46 per cent and in seven weeks it had increased to approximately 38 to 55 per cent, depending upon the method of storage.

However, when prepupae were stored from three to four weeks the females which emerged were permanently injured and their egg-laying capacity was much reduced.

Pupae are unable to withstand even a moderate period of retardation. After the second week, mortality rose to about 66 per cent and most of the eggs subsequently laid failed to hatch.

Low temperature retardation of the various stages in the life cycle of the blowfly, although a convenience in cultural technic, causes such a high mortality that its use is considerably limited. It appears to be best adapted to short storage periods or when the convenience of continued storage is sufficient to counterbalance the losses.

BACTERIUM MELANINOGENICUM²

M. SHEVKY, A.B., C. KOHL, B.S., AND M. S. MARSHALL, PH.D.
SAN FRANCISCO, CALIF.

SINCE the brief description of *B. melaninogenicum* by Oliver and Wherry,¹ in 1921, there have appeared several studies of this organism. Attention has been focused on the subject because of two established facts, that the organism produces an abundance of a dense black melanin-like pigment, and that it is found in a variety of situations in the human body, both normal and pathologic. Pulmonary abscess is only one of the various pathologic conditions in which the organism is frequently encountered, but it is an example of a number of processes in which the etiology is obscure, and in which the developed affection represents more than likely a complex secondary infection. Since relatively little has been reported on *B. melaninogenicum*, since it normally exists in various parts of the body and thus is present when opportunity to invade exists, since it acts on blood substance, and since studies of pulmonary abscess here and elsewhere frequently revealed this organism in the abscess, the study of the type seemed to offer one of a number of possible avenues of approach.^{2, 3, 4, 5} The possibility of primary invasion was open. The potential rôle in infections in which the organism was a secondary

¹From the Department of Bacteriology and the Department of Surgery, University of California Medical School, San Francisco.

Received for publication, May 3, 1933.

Added by The Lillie Spreckels Wegforth Donation for the study of pulmonary abscess.

invader seemed worth study. The concept of the etiology and development of pulmonary abscess has been considered elsewhere.⁶

The purpose of the present report is to indicate the biologic characteristics of *B. melaninogenicum* determined in the course of the investigation above mentioned. It will be apparent that no evidence has been observed which would lead one to suppose that this organism is a significant etiologic agent in what becomes a mixed infection, nor that it has any significant part in the complex changes which obtain in the developed focus.

MORPHOLOGY

The organism is generally described as a small coccobacillus, gram-negative, nonsporulating, and nonmotile. In smears directly prepared from clinical material it frequently appeared as an encapsulated diplococcus (C. K.). In liquid medium pairs or clumps of the typical small cells appear, along with narrower rod forms and slender, slightly bent filaments, occasionally ten or more times the ordinary length. The organisms are somewhat larger and more definitely rodlike when grown on solid medium, and the morphology is more nearly constant. A considerable number of observations seem to indicate that the smaller rod forms take a bipolar stain or appear vacuolated. The cells are not acid-fast. Although measurements are likely to be misleading, those made on what was considered to be a normal or typical smear indicated a length of from 0.5 to 0.9 μ and a width of from 0.3 to 0.5 μ for the small types. Larger forms of 0.6 by 1.4 μ were not uncommon and these dimensions are not maximum.

Colonial morphology was not distinctive, except for pigment formation. Colonies appear smooth, shiny, moist, convex, and with an entire edge. Pigment varied from a light or deep coffee brown to jet black, and appeared microscopically to be accumulated densely at the center with a clear narrow surrounding zone. Moist colonies could be lifted off entirely, and older colonies were drier and disintegrated when touched with a loop. Hemolysis on blood agar was noted in pure cultures four to seven days old, at a point where growth was heavy or confluent. In mixed culture there appeared to be more marked hemolysis. Under good conditions, colonies attained a diameter of several millimeters.

ISOLATION

Clinical material from which this organism may be obtained frequently is usually heavily loaded with a variety of organisms. As elsewhere reported, although initial growth is not difficult, isolation in pure culture is hazardous. Heart hormone agar, P_H 7.4, with 5 per cent defibrinated rabbit blood, as suggested by Burdon,⁷ was satisfactory, as were other media. Freshly poured moist plates, inoculated immediately, were found to be most favorable. Slants, naturally moister, were used very successfully in rapid work. Plating technique, with repeated selection of colonies and transfer, was the only means found for isolation, although less time-consuming procedures were sought.

Other media on which growth was secured were:

1. Bordet-Gengou's medium.
2. Blood clot digest agar.
3. Veal infusion agar with 5 per cent rabbit or human blood; with human serum; with blood and 0.2 per cent cystine or 1 per cent glucose.
4. Brain broth with whole human blood; with human serum; with 30 per cent ascitic fluid.
5. Dehydrated (Difco) brain agar; with or without human whole blood or serum.
6. Extract ("Standard Methods") agar with rabbit or human blood, rabbit serum (P_H 6.4).
7. Liver hormone agar.
8. Semisolid (0.2 or 0.3 per cent) agar, with blood, serum, or ascites.
9. Loeffler's medium.
10. Beef heart broth with 0.05 or 0.1 c.c. whole blood per tube, or 30 per cent ascitic fluid; or without enrichment, with long established cultures.

No growth was secured with brain broth or veal broth or with dehydrated brain-heart broth (Difco) plus serum, blood, ascitic fluid, or adrenalin. Stimulating substances were not noted in experiments with autoclaved sputum, yeast filtrate, or carotin. In mixed cultures used in isolation a small amount of adrenalin^s seemed to produce larger and moister colonies, although no effect was noted with pure cultures.

Anaerobic conditions were necessary for isolation and growth, although the organism did not appear to be an absolutely strict anaerobe. The choice of method appears to depend on convenience. Hydrogen replacement (Boez), phosphorus jars (Varney), deep shake tubes, Veillon tubes, Fortner plates, Buchner tubes with pyrogallol, semisolid agar, deep brain broth tubes (enriched), Wright's tubes (and Petroff's plates prepared as Wright's tubes), and Krumwiede's plate method, all were successfully used.

SPECIMENS YIELDING B. MELANINOGENICUM

The organism has been described as common in the normal mouth and external genitalia, and in pathologic material from mixed infections. Isolations were made in the course of this study from the mouth, from a number of cases of pulmonary abscess, from seven uterine swabs, from one psoas abscess, from two ischiorectal abscesses, from one parotid abscess, from one submaxillary abscess, from one abscess following tooth extraction, from one open mastoid, from one colpotomy, from one liver abscess following perforation of gastric carcinoma, from one empyema, from one gunshot wound perforating the stomach, from one open leg ulcer, and from one perineum. Pigmented colonies were recognizable usually after four to twelve days, with an average of six days and a maximum of twenty-one days of incubation.

GENERAL PHYSIOLOGY

The optimum temperature for growth appeared to be 37° C. Exposure to 60° C. for ten minutes and longer rendered a seventy-two-hour broth culture nonviable. Heavy inoculations were found to be advisable for transfer, particularly in shifting from solid to liquid medium. The organism sometimes developed slowly on primary growth, and thereafter required frequent trans-

fer until well established, as Burdon suggests. Intervals of six to ten days were successful, and viability was demonstrated after twenty-four days' incubation in semisolid blood agar; after thirty-two to thirty-seven days in brain 30 per cent ascitic fluid broth, but not after sixty days in the refrigerator; and after twenty-eight days but not after six weeks when kept at 37° C. on solid medium. A very disagreeable odor of putrefaction was noted, somewhat cheesy with solid media, and butyric with liquid and semisolid amount of gas was observed in pure cultures in brain ascitic fluid broth and media (enriched with ascitic fluid), in which the odor was greatest. A small in beef heart blood broth one to three days after inoculation.

Fermentation, with acid and gas, was observed, after overcoming some technical difficulties, with dextrose. Sodium phosphate extract broth¹ enriched with ascitic fluid or rabbit serum, proved satisfactory. Not all media allow fermentation. Maltose, levulose, and mannite occasionally yielded acid without gas; sucrose, lactose, dextrin, and galactose were never observed to break down.

Using ZoBell's method⁹ no nitrate reduction was demonstrated; that is, nitrite tests were negative and nitrate tests remained positive. Indol tests were positive. Rather uniquely, brom cresol purple milk was acidified. It was also peptonized, as might be expected from proteolytic properties mentioned by Burdon. Slight liquefaction of Loeffler's medium was noted, partial digestion of brain particles in brain broth, and slight blackening of beef heart particles in beef heart broth after three or four days. Liquefaction of gelatin was not demonstrated although repeated tests were made, a discrepancy with reported results. Using brain 30 per cent ascitic broth, the liberation of H_2S was very marked.

PIGMENT PRODUCTION

The characteristic intense black pigment appeared to arise solely from blood substances. Repeatedly cultures produced pigment on blood medium, lost this property on medium without blood, although growing vigorously, and regained it when returned to a blood medium. In serum agar a late production of a reddish brown pigment appeared. Ascitic fluid and adrenalin appeared to be lacking in essential bases. Pigment appeared to be deposited after four or five days' growth (earliest noted, forty-two hours) and the development of a visible colony, first as a central brownish zone, later increasing to jet black and covering the whole colony. Bordet-Gengou's medium seemed especially favorable to pigment production, but no substance found chemically more definite than blood seemed to furnish the key to its development. When washed off with distilled water and dried on filter paper, it was found to be insoluble in distilled water, methyl alcohol, ether, chloroform, acetone, N/1 HCl, dilute ammonia; partially soluble in 10 per cent KOH (yellow solution, but pigment remained as granular masses), N/2 $NaCO_3$, and N/1 NaOH; soluble in acidified methyl alcohol (0.2 c.c. HCl to 5 c.c.) and in glacial acetic acid (pink color). Observations indicating that the pigment is toxic toward the organisms or that it is formed coincidentally with a toxic substance, were not convincing.

SEROLOGY

Extensive serologic tests were not considered advisable for the problem at hand. Agglutination tests, however, were performed with serum from rabbits given 11 injections intravenously in amounts of 1 to 4 c.c. of suspensions as high as 1 per cent. Antigen suspensions were made up to 0.25 per cent, preserved with Merthiolate. Agglutination set-ups were incubated two hours at 56° C., overnight at 37° C. and on ice for twenty-four hours. Control checks remained negative, and titers reached 1:1280 with +++ reactions, with some agglutination at 1:10,240 with one serum. Clumping was granular rather than flocculant. In support of this definite agglutination reaction a miscellaneous collection of strains was brought together and tested against specific anti-serum. Although the titers were not equally high with all strains, there was no reason to postulate the existence of a wide variety of serologically heterogeneous strains.

PATHOGENICITY

B. melaninogenicum was used, both in pure cultures and in mixed cultures, in experimental work on pulmonary abscess, the results of which will be reported elsewhere (Stevens and Shevky). No evidence was found that this organism had any invasive capacity, however, which is consistent with the observations mentioned herein. Burdon found⁷ with one strain an extensive cutaneous gangrene following subcutaneous inoculation, without septicemia, but with death in forty-eight hours. Most of the meager evidence available indicates a lack of pathogenicity.

Control checks were not extensive. Three each of rabbits, guinea pigs, rats, and mice were cultured around the gingival margins, and *B. melaninogenicum* was found in one rabbit. Bacteriologic studies of experimentally inoculated animals did not lead one to suspect that the organism was particularly common as a commensal in local stock animals.
